Abstract

Rock glaciers contain valuable information about the spatial and temporal distribution of permafrost. The wide distribution of these landforms in high mountains promotes them as useful archives for the deciphering of the environmental conditions during their formation and evolution. However, age constraints are needed to unravel the palaeoclimatic context of rock glaciers, but numerical dating is difficult. Here, we present a case study assessing the potential of luminescence techniques (OSL, IRSL) to date the inner sand-rich layer of active rock glaciers. We focus on the signal properties and the resetting of the signal prior to deposition by investigating single grains. While most quartz shows low signal intensities and problematic luminescence characteristics, K-feldspar exhibits much brighter and well-performing signals. Most signals from plagioclases do not show suitable properties. Luminescence signals far below saturation indicate distinct but differential bleaching. The finite mixture model was used to determine the prominent populations in the equivalent dose distributions. The luminescence ages represent travel times of grains since incorporation into the rock glacier and hence, minimum ages of rock glacier formation. Luminescence ages between 3 kyr and 8 kyr for three rock glaciers from the Upper Engadine and Albula region (Swiss Alps) agree well with independent age estimates from relative and semi-quantitative approaches. Therefore, luminescence seems to have the potential of revealing age constraints about processes related to the formation of rock glaciers, but further investigations are required for solving some of the problems remaining and reducing the dating uncertainties.

Keywords: Rock glacier, Luminescence dating, OSL, IRSL, Single grains, Alps

1. Introduction

In order to set modern climate-related observations into long-term perspectives, environmental proxies recorded in various natural archives are needed to reconstruct past climate and landscape evolution. In mountain areas, highly climate sensitive glacial and periglacial processes are the main agents modulating the Earth's surface. These regions are also of special interest because within short horizontal distances they host climatic regimes similar to those of widely separated latitudinal belts (Beniston et al., 1997; Beniston, 2005). The resulting sensitivity to changes in environmental conditions constitutes mountain areas to be among the key regions for observing, reconstructing, and finally predicting climate change and its impact on surfaces processes.

Extensive areas of high mountain regions are governed by permafrost conditions with rock glaciers marking the lower boundary of its distribution (Haeberli et al., 2011).

Rock glaciers comprise perennially frozen and ice-rich debris on non-glaciated mountain slopes that creep steadily under the influence of gravity (e.g. Haeberli et al., 2006). Active rock glaciers of the Alps (i.e. containing ice and actively deforming) are assumed to have formed and evolved during the Holocene (Frauenfelder et al., 2005). Relict forms at lower altitudes have lost their ice content and do not creep anymore. As they initially must have formed under permafrost conditions, they have a considerable potential for constraining past climatic conditions (Ballantyne et al., 2009). However, the deciphering of rock glaciers as geo-archives requires a temporal assignment by means of numerical dating.

Haeberli et al. (2003) suggest a concept of combined relative and (semi)quantitative techniques for rock glacier dating. Photogrammetric measurements of surface flow fields, weathering rinds, Schmidt-hammer rebound, and lichenometry indicate increasing surface ages towards the front. Extrapolation of present day velocities may indicate surface ages of 5 - 6 ka (Kääb et al., 1998) or 3 - 5 ka (Frauenfelder et al., 2005), but with uncertainties related to possible changes in palaeo-velocities or even phases of flow inactivity. Although the relative and semi-quantitative approaches confirm the concept of rock glaciers

developing at millennial time scales, spatial variations in flow velocities indicate various site- specific effects (e.g., local slopes, ground temperature, rock types). This emphasizes that the interpretation of relative age constraints and their comparison between study sites requires calibration based on numerical dating. Radiocarbon dating of the only organic remnants encountered during drilling at the Murtl rock glacier yielded a ^{14}C age of (2.3 ± 0.1) ka BP (Haeberli et al., 2003). From the rock glaciers Murtl, Muragl and La Veduta (Upper Engadine, Switzerland) preliminary results indicate problematic luminescence properties due to low signal intensities in quartz (90 - 200 μm fraction). Although no detailed datasets are presented, Haeberli et al. (2003) state that all datable samples give ages between about 4 ka and 8 ka. Böhlert et al. (2011b,c) suggest two different permafrost activity phases since the Lateglacial: one phase after the ice retreat following the Younger Dryas and the other in the Holocene. Based on cosmogenic nuclide dating and weathering rinds in the French Alps, Cossart et al. (2010) distinguished three main generations of rock glaciers since the Lateglacial: the first one around 11 ka or 12 ka, the second around 2 ka or 3 ka, and the last one in more recent times.

Over the last decades, advances in optically stimulated luminescence (OSL) and infrared stimulated luminescence (IRSL) techniques broadened the field of applications in sediment dating (e.g., Lian and Roberts, 2006; Bateman, 2008; Fuchs and Owen, 2008). The main advantages are that these methods directly date the material's last light exposure associated to the timing of deposition, and that they use almost ubiquitously present quartz (OSL) and feldspar (IRSL) for dating. Concerning the dating of rock glaciers, luminescence techniques are not reliant on organic material necessary for radiocarbon dating, and are independent of stable surfaces as required for cosmogenic nuclide dating. However, the OSL properties of quartz, the mineral chosen in most applications, are often problematic in mountainous areas (e.g., ?). This is apparently related to the fact that OSL signals suitable for dating result from sensitisation during repeated sediment transport/deposition cycles (??), but with the exact physical processes in the crystal lattice being poorly understood (cf. ?). This problem is not known to apply for feldspars, but the signal of this mineral can be less stable, and such fading of the signal can cause underestimation of the determined age (?). Furthermore, the IRSL signal from feldspar is expected to bleach more slowly than the OSL from quartz (e.g., ?).

In the context of glacial and periglacial environments and their related transport processes, it has to be considered that insufficient light exposure may not completely bleach the pre-existing luminescence signals (e.g., Fuchs and Owen, 2008). Such incomplete bleaching causes residuals that form part of the measured signal and, if not detected and excluded, lead to an overestimation of the palaeodose and, accordingly, of the calculated age. However, it has been shown that poorly bleached sediments are usually composed of grains with different bleaching levels (Duller, 1994). It is possible to detect differential bleaching when measuring the signal of small aliquots or single grains, where it is expressed by the spread of replicate measurements (e.g., Wallinga, 2002; Duller, 2008). Statistical approaches are then applied to extract the true burial dose (e.g. Galbraith et al., 1999; Bailey and Arnold, 2006). To ensure a correct extraction of the well-bleached signal portion, such approaches have to account for sample specific parameters that have an effect on the expected spread of data without differential bleaching (e.g., instrumental error, material-inherent variability, microdosimetry).

In this study, we investigate the potential of both, quartz OSL and feldspar IRSL (K-feldspar, plagioclase) focussing on single grain measurements to date three active rock glaciers in the Piz Julier area and in the Val Tschitta, Swiss Alps (Fig. 1). For the Gianda Grischa and the Suvretta rock glacier age estimates are available from streamline interpolations and relative dating measurements (Frauenfelder et al., 2005). Due to the relatively simple geometry and the availability of relative age estimates, the Salteras rock glacier was chosen as an additional site. Firstly, we describe rock glacier sedimentary dynamics and discuss the relevance of processes involved in grain input and transport within rock glaciers for the interpretation of luminescence ages. Secondly, we present the luminescence signals of quartz OSL and feldspar IRSL measurements and statistically analyze the dose distributions for prominent populations. Finally, we discuss the derived grain travel times in the context of the process related assumptions and accordingly the potential of luminescence techniques to constrain the age of rock glacier formation.

2. Methodological aspects of rock glacier dating

2.1. Formation and dynamic of rock glaciers

According to Barsch (1996) three main aspects define active rock glaciers: the form of a lobate or tongue-shaped body, the perennially frozen unconsolidated material supersaturated with interstitial ice and ice lenses, and the process of down-slope creep as a consequence of deforming ice contained in them (cohesive flow). Berthling (2011) emphasizes the cumulative deformation by long-term creep of ice/debris mixtures under permafrost conditions. All rock glaciers studied in this work formed in crystalline areas and can be described as 'bouldery rock glaciers' with mean boulder diameters of 15 - 20 cm (Böhlert, 2010), following the classification scheme of ?. They are furthermore classified as valley floor/tongue shaped rock glaciers according to ? and ?.

Rock glaciers form when the ice content of perennially frozen debris or talus on slopes exceeds saturation, and the body of debris and ice starts deforming slowly (creeps) under gravitational stress (Haeberli et al., 2006). Such creeping, ice-rich rock glacier bodies develop at slopes
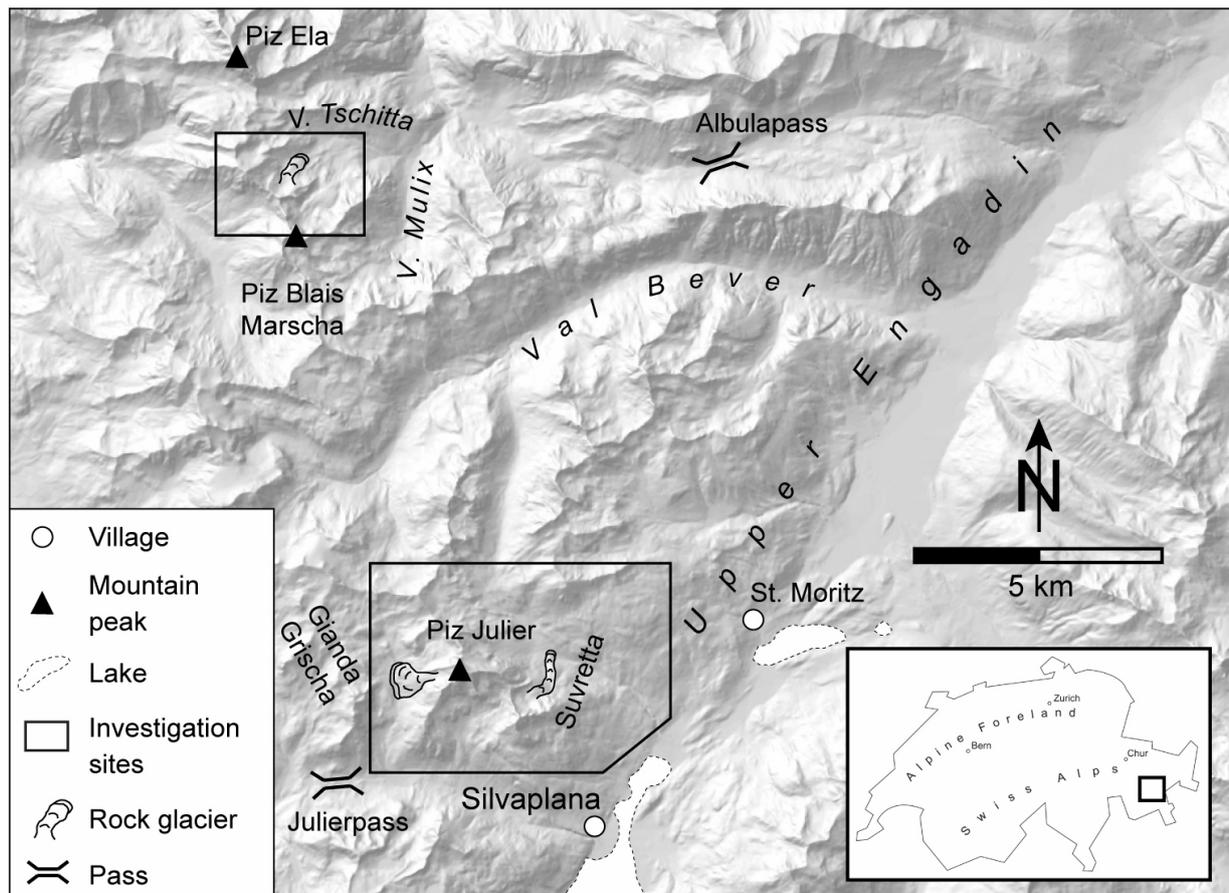

Figure 1: Regional setting of the study area.

where a concave area favors the accumulation of material from adjacent steep bedrock walls (Fig. 2). The processes leading to material and ice accumulation are numerous, and complex interactions with glaciers are possible (Haeberli et al., 2006), sometimes making a clear identification of the landform challenging (Böhlert, 2010; Berthling, 2011). For instance, the source material can be provided by ice-cored moraines ('moraine- derived' rock glaciers) or by debris flows and solifluction. Separation processes result in the typical sorting of grain sizes, represented by boulder enrichment in the top and bottom layer whereas the fine-grained material concentrates in the inner part. The upper, normally boulder-enriched part represents a highly heterogeneous layer that is strongly influenced by the thickness and temporal distribution of the snow cover (Haeberli et al., 2006). Characteristic active layer thicknesses range from a few centimeters to a few meters (**?**). In the fine-grained (Fig. 2 and Fig. 3) and often ice supersaturated material of the inner parts energy fluxes are mainly conduction-controlled. The creep of rock glaciers can be described by 'caterpillar-like' flow behaviour (Fig. 2): boulders at the surface fall down at the over-steepened front and are subsequently overridden by ice-supersaturated, fine-grained material.

2.2. Sediment dynamics and relevance for luminescence dating

According to the model of rock glacier dynamics described above, the material available for dating derives either from the upper boulder-rich layer, principally suitable for cosmogenic nuclide dating, or from the inner fine-grained layer that has the potential to be dated by luminescence methods. The 'caterpillar-like' flow results in an age inversion of the boulder enriched layers: at the surface, the age of the blocky material increases towards the front, while for the overridden base-layer the opposite applies (Haeberli 1985; Fig. 2). Beside inaccessibility of the oldest boulders in the base layer, additional problems for numerical dating (i.e. cosmogenic nuclides) are related to the unstable exposure of boulder surfaces and possible inheritance of cosmogenic nuclides from previous exposure. The layer of fine-grained material at the front of active rock glaciers represents buried particles of the long-term creeping, perennially frozen talus (Haeberli et al. 2003, Fig. 3). Dating this inner, fine-grained layer will give the time when grains were incorporated into the rock glacier. As a consequence, luminescence ages of such layers will represent travel times, i.e. the time since the signal was reset during deposition on the rock glacier surface followed
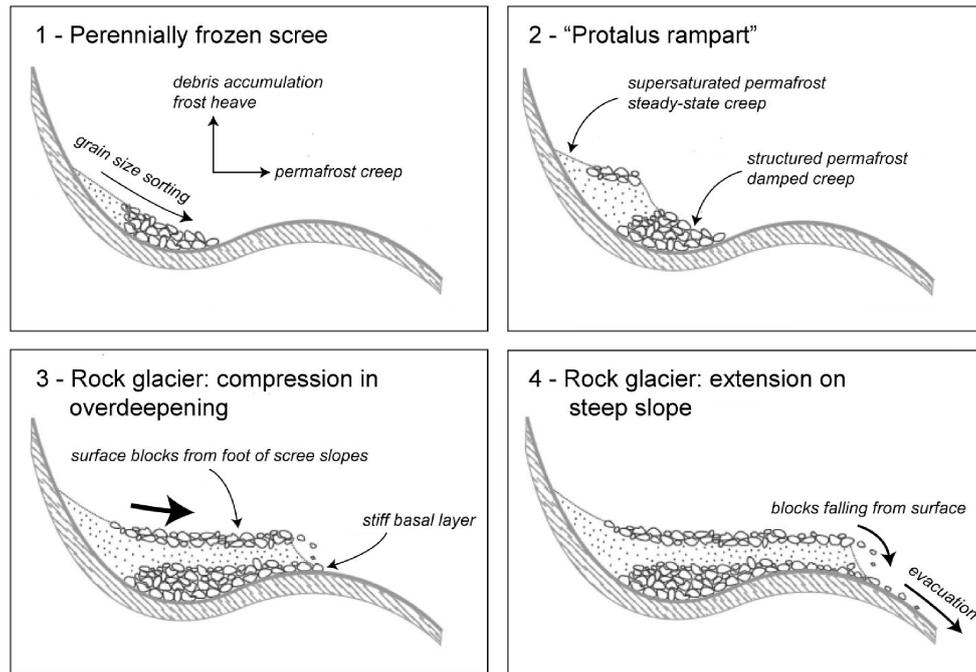

Figure 2: Idealised sequence of rock glacier development (after Haeberli et al. 1998.

by shielding and signal growth as long as grains are transported within the rock glacier body.

In this context, two main processes need to be considered regarding their effects on the luminescence signal: (1) grain pathways into the rock glacier with corresponding characteristic bleaching history, and (2) grain transport within the rock glacier body affecting sediment mixing and signal growth. It is important to note that luminescence ages, due to the input paths of fine-grained material described above, will likely only represent the minimum age of the rock glacier. Only in the case of dominant material input and sufficient bleaching at the rock glacier's rooting zone, undisturbed signal growth during grain transport towards the front, and under the assumption that no fine grained material is eroded at the front, the travel time might indicate the age of rock glacier formation.

Possible process-related effects on the luminescence signal are summarized in Table 1. The accurate determination of the travel time fundamentally relies on the level of signal resetting prior to grain incorporation, related to how the fine-grained material was supplied to and incorporated into the rock glacier. Different input pathways lead to distinct populations of grains with characteristic bleaching histories and potentially representing different times of incorporation. In principal, material available for rock glacier aggregation may be derived from headwall erosion of bedrock that surrounds the rooting zone, from aeolian sediment supply, from basal uptake or from internal grain size reduction. The short transport distances from surrounding headwalls might cause incomplete bleaching, while prolonged surface retention times of grains due to,

for example, perennial snowfields or avalanche residues as well as aeolian input will likely deliver well-bleached grains. Potential sources of incompletely bleached grains are basal uptake of material and internal, permafrost-related grain size reduction resulting from the shear stress of creeping, ice super-saturated sediment.

After incorporation into the rock glacier, luminescence signals are expected to reveal an age-distance relation with increasing signal towards the front of the rock glacier (Fig. 3), but sediment mixing might disturb this simple relation. Causes for vertical and lateral sediment mixing might be related to gravitational creeping permafrost and corresponding uncertainties in grain trajectories. Possible mechanisms of vertical sediment mixing involve meltwater that may transfer grains from the surface of the rock glacier into deeper parts. The input of material along crevasses (extension/compression zones) similarly promotes the vertical and lateral mixing of surface-derived grains with older sediment layers.

Apart from uncertainties due to the grain pathways, processes related to the gravitational creep of ice super-saturated material might cause variations in the efficiency of the dose rate and with regard to the shielding against cosmic radiation. Potential micro-dosimetric variations mainly relate to uncertainties in the water/ice content and especially in its distribution. Ice super-saturation, segregated ice or ice lenses can cause inhomogeneity in the distribution of radionuclides in the fine-grained matrix and may affect the actual dose rate of each individual grain.

Considering the possibility of both, different input-related bleaching histories and transport-related sediment
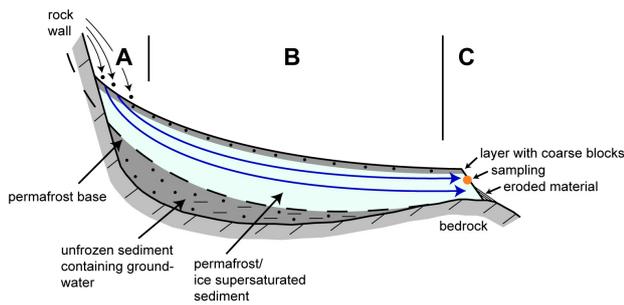

Figure 3: This example shows a tallus-derived rock glacier below a rock wall. The top layer with coarse block approximates the active layer. The blue arrows represent idealised trajectories of single grains subsequently removed at the front for lumines- cence dating. The measured age theoretically is the time the grain needed to travel this distance within the rock glacier body, protected from daylight. A = rooting zone (grain incorporation); B = rock glacier lobe (grain transport); C = rock glacier front (sampling). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article).

Table 1: Potential processes related to rock glaciers and their effects on the luminescence signals.

Process	Effect
Deposition and incorporation:	
Aeolian input onto rock glacier surface	Supply of well-bleached grains
Input from short distance transport (e.g. from mass movements)	Insufficient light exposure (incomplete bleaching)
Grain retention on rock glacier surface (e.g. due to snow cover)	Prolonged light exposure, well-bleached grains
Internal source of fine material (grain size reduction by permafrost)	No or insufficient light exposure (partial bleaching)
Basal material uptake (incorporation of older sediments)	No or insufficient light exposure (Incomplete bleaching)
Transport:	
Horizontal sediment mixing (e.g., by meltwater)	Mixing with younger grains
Vertical sediment mixing (e.g., crevasses)	Mixing with grains, e.g., derived from aeolian material supplied to the rock glacier surface
Trajectories of individual grains (grain transport at constant depth?)	Uncertainties related to shielding against light exposure as well as cosmic dose rate
Permafrost variability	Uncertainties in dose rate efficiency and paleo-water/ice content

mixing, we expect to measure luminescence signals that reveal different grain populations within the same sample. The determination of the travel time of grains from the mixed grain populations requires the correct detection and exclusion of signals from subsequently incorporated younger grains (age underestimation) and grains incompletely bleached prior to burial (age overestimation). The accurate and precise determination of the well-bleached grain population relies on reliable luminescence properties (e.g., dose-response relation, signal sensitivity and reproducibility) and at least some grains completely zeroed before incorporation into the rock glacier. Because the material loss at the rock glacier front is difficult to evaluate, the travel times based on the well-bleached grain population represent minimum ages of the rock glacier formation. To reduce the relative contribution of the external dose rates and related uncertainties to the total dose rate, we aim at comparing the results for three minerals with differing internal dose rates (quartz, K-feldspar, and plagioclase; cf. Barre and Lamothe 2010).

3. Study sites

The study sites are located in the eastern part of Switzerland (Upper Engadine). Greenish 'Albula Granite' comprised of quartz, plagioclase (in places altered to epidote), K-feldspar, biotite and rarely hornblende is the dominant rock type in the area (cf. **?**). The reconstructed Last Glacial Maximum (LGM) ice surface geometry shows that the area was situated near the 'Engadine ice dome'. Trimline and other erosional features indicate that during the LGM the Albulapass formed a northward transfluence with ice flowing from the Engadine into the Rhine river system (Florineth, 1998; Florineth and Schlüchter, 2000; Bini

et al., 2009). As a result of the highly unstable climate during the Lateglacial (c. 19 - 11.5 kyr) and the early Holocene, a variety of climate-related landforms developed in mountain areas of the Alps. A geomorphic map of the region describes the landforms and the different glacier stages after the LGM (**?**). The glacier stages were numerically dated measuring in-situ produced [10]Be in boulders on moraines, polished bedrocks, and roches moutonnes (Ivy-Ochs et al., 1996; Böhlert et al., 2011b,c). Distinct glacier stages could be attributed to the Daun (Oldest Dryas) phase (14.9 - 1.8 kyr) and several Egesen phases (Younger Dryas). At high-elevation sites near the LGM trimline, [10]Be exposure ages of glacially modified bedrock are between 11.2 kyr and 13.5 kyr (Böhlert et al., 2011b). This suggests the persistence of long-lasting small local ice caps after the breakdown of the LGM ice domes or, alternatively, a reformation of ice perhaps during the Younger Dryas. Exposure ages from a glacially polished rock barrier showed that this area was ice-free at the end of the Younger Dryas ((9.0 ± 0.7) kyr and (11.9 ± 0.9) kyr; Böhlert et al. 2011b). In general, two different altitudinal levels of rock glaciers are recognized. A first generation (inactive rock glaciers) reaches altitudes down to 2000 - 2300 m a.s.l.. A second generation (active rock glaciers) is usually above 2400 - 2700 m a.s.l. (depending on exposure). Surface exposure dating (SED) of a roches moutonnes using [10]Be, ^{14}C dating of a peat bog, palynological investigations as well as glaciomorphologic mapping (**?**) delimited the maximum age of the Lateglacial permafrost activity that apparently started shortly after the Younger
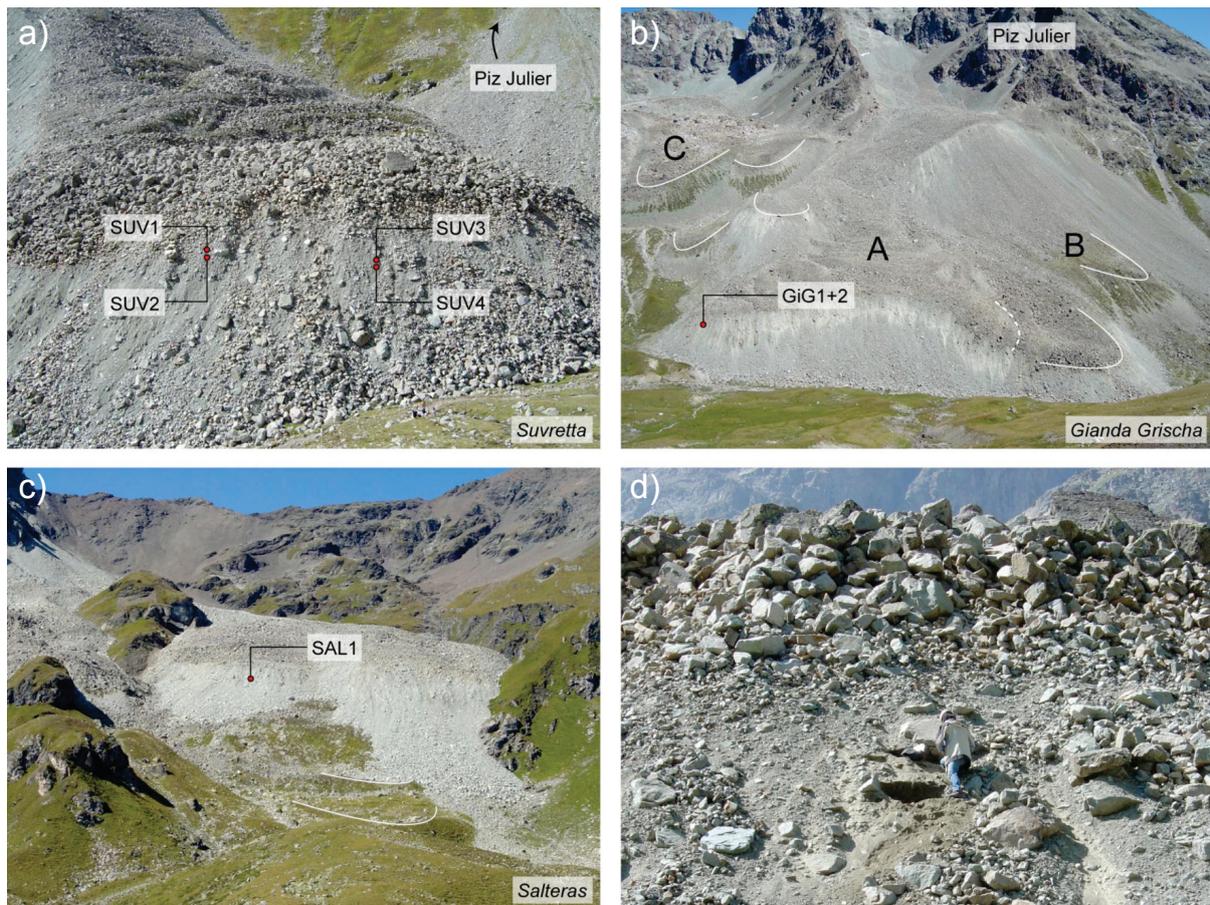

Figure 4: The rock glaciers sampled for luminescence dating are shown. Sampling locations are represented by red dots. Samples are ideally taken between the coarse blocks on the surface and the eroded and accumulated material at the lower part of the slope. This zone at the rock glacier Gianda Grischa is especially clearly visible as a white band. Digging below big boulders provides a better slope stability and increases the possible penetration depth (lower right, rock glacier Suvretta). Neighbouring and associated (potentially) inactive and relict creeping forms are indicated by white lines. The dashed line on the rock glacier Gianda Grischa approximates the zone where an older part is overrun by a more active lobe. At this site, three main parts can be distinguished: (A) active rock glacier, (B) older, possibly relict part, (C) inactive rock glacier (based on Frauenfelder et al. 2008). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article).

Dryas (about 11.6 kyr; Böhlert et al. 2011a). Soil analyses support these time constraints for the second activity phase that hypothetically started sometime around 6 kyr ago and continues today (Böhlert et al., 2011a).

Three active rock glaciers were investigated (Fig. 1). Age constraints from relative and semi-quantitative methods, summarized in Frauenfelder et al. (2005), enable to set the here-measured luminescence ages into context. Age estimations mainly based on streamline interpolations were the reason for the choice of the Gianda Grischa and the Suvretta rock glacier. A comparably simple geometry in combination with a dataset from relative dating approaches was the reason for the choice of the Salteras rock glacier as an additional site. The sampling sites on each rock glacier are shown in Figure 4.

3.1. Suvretta

The Suvretta rock glacier is characterised by a more than 1 km long, relatively thin monomorphic body creeping out of the cirque below the Piz Albana, in closest vicinity to Piz Julier (Fig. 1 and Fig. 4a). It covers an altitudinal range of about 500 m, with a starting zone at around 2800 m and a front position at 2300 m. The rock glacier front is undercut by the mountain stream coming down the Suvretta valley (?). The thickness of the permafrost body ranges from almost 100 m in the upper part to around 20 m near the front, as determined by geoelectric techniques. Active layer thickness does usually not exceed 2 m (?). The length profile is S-shaped: The slightly dipping root zone changes at 2600 m to a steep zone of extending flow in the middle part, flattening again towards the valley bottom with a zone of compressing flow in the tongue area. The area around the rock glacier was most

probably not influenced by extensive ice during the end of the Lateglacial and the Holocene (??). The corresponding sheet from the Siegfried map (sheet St. Moritz, 1875) does not indicate that the cirque was occupied by ice masses during the Little Ice Age (LIA). However, the presence of (perennial) ice or snow patches cannot be ruled out.

Photogrammetric techniques determined horizontal surface displacement rates of up to $2\,\mathrm{m\,a^{-1}}$ and a surface age at the front of approximately $3\,\mathrm{kyr}$ (Kääb et al., 1997, 1998; Frauenfelder et al., 2005). Reconstructed streamlines represent the trajectories of individual particles on the surface. Considering that the overall advance rate of the rock glacier can be much smaller, the calculated ages have to be interpreted as minimum ages. The maximum age (travel time) can be 2 - 5 times higher (Kääb, 2005). Both Schmidt-hammer rebound values 'r' (Castelli, 2000) and weathering rind thicknesses (?) show a clear trend following the length profile and, in combination with the estimated ages from photogrammetry, allows for calibration. The oldest parts near the tongue yielded weathering rind thicknesses between $2.5\,\mathrm{mm}$ and $3\,\mathrm{mm}$ and r-values ranging around 35, respectively (Frauenfelder et al., 2005). The values are typical for rock glaciers having a maximum surface age of several thousand years that suggest Holocene rock glacier formation (Böhlert et al., 2011a).

3.2. Gianda Grischa

The double-tongued Gianda Grischa rock glacier (Fig. 1 and Fig. 4b) on the western slopes of Piz Julier is, from a geometrical point of view, the most complex one. Multiple generations of lobes with different activity stages are distinguishable. Several situations show younger active parts overrunning older inactive or even relict parts. This is especially pronounced at the orographic left tongue. In order to reduce complexity, we chose the right tongue for sampling. The southern margin of the middle part of the rock glacier is steeply sloping down towards SW, in Figure 4b identifiable as a bright area clearly contrasting the more gently sloping surface of the rock glacier.

To the north of this active polymorphic rock glacier an inactive exemplar can be separated. Its location in a flat niche was occupied by a small glacier during the LIA, while the cirque of the active rock glacier was ice-free at this time (?; Siegfried map, sheet St. Moritz, 1875). According to ?, well-pronounced Egesen-equivalent moraines near Julierpass indicate a glaciation during the Younger Dryas. Two-dimensional electrical resistivity tomography (ERT) surveys showed unusual high active layer thicknesses up to 4 - 5 m. Typical values in this region are 3 - 3.5 m on rock glaciers and 4 - 5 m in rock walls. Photogrammetry yields lower surface displacement rates compared to the rock glacier Suvretta, with an average velocity of 0.4 - $0.5\,\mathrm{m\,a^{-1}}$ and maximum values around $0.8\,\mathrm{m\,a^{-1}}$. The minimum estimated surface age is 4 - 5 kyr (Frauenfelder et al., 2005). Schmidt-hammer measurements show no clear trend. This may be a result of boulders being rearranged under the influence of gravity in the steep part of

the rock glacier, causing a reset of the 'clock' (Frauenfelder et al., 2005). Weathering rinds, however, show a development with increasing thicknesses towards the front, at least on the orographic left side (?). Maximum values (median, mode) are in the range of $1.5\,\mathrm{mm}$ to $2\,\mathrm{mm}$. This trend is not as clear on the orographic right side, but the measured values are in the same range, indicating a similar age structure on both sides. Related to the age estimation, rind growth rates are about half as high as in the case of the rock glacier Suvretta, although made up of the same source material (Frauenfelder et al., 2005).

3.3. Salteras

The Salteras rock glacier, originating from the NE-oriented cirque to the east of Piz Salteras, shows a rather simple geometry without zones of pronounced compressing or extending flow. The long profile is slightly convex with an increasing slope angle towards the tongue, which is about to creep over a steep grassy slope. The front is thereby divided into two individual lobes. In front of the talus apron, several vegetation covered lobe-shaped forms are visible (Fig. 4c). These might be interpreted as remnants (ridges in a compressing zone or front?) of a collapsed relict form, indicating that the rock glacier Salteras has experienced several activity phases. Lacking lichen coverage and weakly consolidated coarse blocks covering the surface suggest an active stage of the rock glacier.

Neither Schmidt-hammer r-values nor modal values of weathering rind thicknesses - both measured in the middle and the lower part of the rock glacier (?) - show a clear trend representing an increasing exposure time to weathering processes towards the front. The high r-values (45 - 50) agree with the very thin and often completely absent weathering rinds. Using the median, there is a trend indeed; still, the values are very small ($<1\,\mathrm{mm}$). This picture of surprisingly fresh and unweathered surface material might be explained by the influence of glacier ice that might have removed the more weathered rocks at the surface. Although the Siegfried map (sheet Savognin, 1887) shows no ice in this position, moraines found in the upper part support the conclusion that at least the upper parts of the rock glacier have been covered by surface ice during the LIA (?).

4. Methods

4.1. Sampling

Rock glaciers were sampled at the talus apron at the front (Fig. 4). To avoid the influence of superficially eroded and reworked material, we chose sampling spots in the upper third of the slope, clearly higher than the visible debris accumulation zones in the lower parts, but below the coarse blocks at the surface. The approximately 40° steep slopes showed a low stability. Digging was carried out whenever possible underneath isolated boulders that protected the sandy matrix to a certain degree from collapsing

immediately. Keeping a minimum distance of 40 cm from the boulder itself, approximately 50 -100 cm of the surface material was removed until fresh sediment was reached. During sampling, an opaque cover served for shielding the sediment from daylight. Horizontal sediment cores were recovered in opaque plastic cylinders and properly sealed for transportation and storage. The surrounding sediment was sampled for gamma-spectrometric analyses of the sediments radionuclide content.

4.2. Determination of dose rate

The radionuclide content of the sediment was determined based on the specific activities of ^{238}U, ^{232}Th and of ^{40}K and daughters by means of low level HPGe gammaspectrometry. Radioactive disequilibria in the ^{238}U-series were evaluated by comparing the specific activities of subsequent radionuclides with focus on ^{222}Rn daughters to identify Rn-loss. The cosmic dose rate was estimated according to latitude, longitude, mean altitude (accounting for the altitude change during grain transport from the source to talus apron) and thickness of the debris coverage above sampling positions. The dose rate efficiency was corrected based on the mineral and sediment density, grain-size, etched layer, and by the assumed palaeowater content. The palaeowater content refers to the measured in situ content compared to saturation values. While the in situ values are attributed to conditions near the front during sampling season, the sample's water saturation provides a reference for previously higher water/ice contents required for the creep process of the rock glacier. Potential uncertainties arise from inhomogeneity in the sediment matrix and distribution of ice (e.g., ice lenses), although the creep process might average out corresponding dose rate variations between grains. To account for the expected high palaeowater content up to super-saturation (associated to actively creeping rock glaciers), the used palaeowater values was set to about two third of the saturation values. To cover possible variations in water content, high errors were included that range from in situ and exceed saturation values.

The parameters contributing to the total external dose rates of the three rock glaciers are given in Table 2. No significant disequilibria are indicated for ^{238}U due to the specific activities of the Rn daughters ^{214}Pb and ^{214}Bi. A lower activity of ^{210}Pb compared to the rest of the decay chain was observed for samples GiG1 and 2, but the effect on age calculation is less than 1 %. For the determination of the mineral-internal dose rate of K-feldspars, a potassium content of (12.5 ± 0.5) % was assumed (**?**) and for plagioclase (2.0 ± 0.8) % (cf. Barre and Lamothe 2010). Investigations on samples from the Swiss lowland reveal very little variation in the internal K-content of K-feldspars (D. Gaar, pers. com.) Based on the measured specific activity of the sediment, the estimated cosmic component and correction parameters the overall environmental dose rate (and luminescence age) was calculated with the ADELE software (**?**). The age and un-

certainty calculation follows the principles described by Aitken (1985).

4.3. Sample preparation

In the laboratory, the samples were treated under attenuated red light. The two outermost centimeters of the sediment cores were removed on each side as these parts could have experienced light exposition during sampling. This material was used to determine the water content (in situ and saturation) of the sample. The material from the inner part of the cylinders was used for the separation of the quartz and the feldspar grains. Sieving isolated the 100 - 200 μm grain size fractions for multiple-grain aliquot and 200 - 300 μm for single grain measurements. The treatment with 10 % HCl and 30 % H_2O_2 removed carbonates and organic matter, respectively. To assure the separation of quartz, K-feldspar and plagioclase, we introduced a feldspar flotation before density separation. The feldspar flotation was carried out in a solution of 0.2 % HF with pH 2.4 - 2.7 to activate feldspar adherence to bubbles that were induced by pumping air through a frit and the foam agent dodecylamine. Both, the enriched quartz and the feldspar froth, were washed in 5 % HCl and then separated due to density with sodium polytungstate (quartz: 2.62 - 2.67 g cm^{-3}; K-feldspar: <2.58 g cm^{-3}; plagioclase: 2.58 - 2.62 g cm^{-3}). The quartz fraction was then etched using 40 % HF for 60 min and the feldspar fraction using 10 % HF for 40 min to remove ~10 mm of the outer, alpha-ray affected rim of the grains. The following cleaning with 37 % HCl (quartz) and 10 % HCl (feldspars) washed out the fluorite precipitates. Final sieving isolated the fractions 90 μm to 160 μm for multiple-grain aliquots and 200 - 250 μm for single grain analyses. The multiple-grain aliquots were prepared by fixing homogenized subsamples of the separated material on aluminum discs within a diameter of 4 mm using silicon oil. Such an aliquot will contain about 200 - 400 grains, of which a small amount will be luminescent (cf. **?**). For single grain measurements, discs with 100 holes arranged in a grid were used, each dimensioned to accommodate a single grain of the size 200 - 250 μm (Bøtter-Jensen et al., 2000).

4.4. OSL measurements of quartz

OSL multiple-grain aliquots measurements were carried out using a RisøTL/OSL reader DA 20 equipped with a Sr-90 beta irradiator (5.6 Gy min^{-1}). OSL emission was stimulated with blue LEDs (470 nm) for 50 s at 125 °C and detected through a U 340 Hoya optical filter. 20 aliquots of samples SAL1 and SUV2 were measured following the single-aliquot regenerative-dose (SAR) protocol (**?**) for quartz. Subsequent to the natural signal, the aliquot-specific dose-luminescence relation was determined based on six regeneration cycles including monitoring of recuperation, recycling ratio, and sensitivity change. Preheat before each OSL stimulation was set to 260 °C and cutheat to 220 °C for 10 s (for details on measurement parameters,

Table 2: Data for dose rate estimation (SAL = Salteras; SUV = Suvretta; GiG = Gianda Grischa; D_{cos} = cosmic dose rate; I = in situ S = saturation; U = used for calculations).

GiG1+2	52.0 ± 4.0	36.5 ± 2.0	705.0 ± 40.0	250	3.4	18.0	12 ± 9	3.6

see Supplementary Material D). For sample SAL1, four additional dose recovery tests (?) were applied to assess the reproducibility of OSL signals in reference to a known laboratory dose. This coefficient of variation (v_{DR}) determines the sample-specific variability of OSL signals inherited from the sample's material and the applied measurement conditions.

Additionally, single grain measurements were performed for samples SAL1, SUV1-4 and GiG1-2 to avoid the averaging effect of luminescence signals from multiple grain aliquots (e.g., Duller, 2008). Single grain measurements improve the distinction between different populations in the dose distribution and allow for assessing the degree of bleaching. Using a RisøTL/OSL Reader DA 15, luminescence emission was stimulated by a green laser (532 nm, ~50 W cm^{-2}) for 2 s at 125 °C and detected through a Hoya U 340 filter. For each sample 2 - 4 discs were measured. For technical reasons, it was not possible to fill the discs (100 grains) completely. Grain counting under the microscope after the measurement confirmed the degree of filling per disc to be 70 % to 90 %. Equivalence doses were determined following the SAR protocol and parameters described above (for details see Supplementary Material D). Dose recovery tests were carried out only for SAL1.

4.5. IRSL measurements of feldspars

IRSL single grain measurements were carried out for K-feldspars (samples SAL1, SUV2-4, GiG1-2). Additionally, plagioclase was measured for SAL1 and SUV4 to test their applicability for dating with respect to the lowered potassium content and corresponding contribution to the internal dose (cf. Barre and Lamothe 2010). The RisøTL/OSL DA 20 reader was equipped with an IR single grain stimulation unit and we used stimulation with an IR laser (830 nm, 150 mW) for 5 s at 30 °C.

Suitable conditions for luminescence emission and detection were evaluated for sample SAL1 by carrying out thermal transfer tests for different preheat temperatures (220, 240, 260 and 280 °C for 10 s) and by applying different detection filters (280, 410, 560 nm). The measurement procedure followed the SAR protocol of ?, but by replacing measurement of the natural signal by measurement of a laboratory bleached (zero dose) sample. Thermal transfer is expressed by the equivalent dose determined by the

SAR measurement (three aliquots for each pre- heat level). This procedure was repeated for each filter, which corresponds to the three typical IRSL emission wavebands of feldspars with different properties (?). According to the results from the thermal transfer tests (Fig. 5), preheat temperature and optical detection filter were set to 280 °C and 410 nm, respectively. Although the signals determined through the 410 nm optical filter are similar to slightly lower for the preheat temperature of 220 °C, corresponding errors suggest less appropriate measurement conditions for both, 10 % as well as 90 % LED power. Generally higher thermal transfer and much higher errors in equivalent dose estimation were detected through the 280 nm and especially through the 560 nm optical filter. Dose recovery tests according to ? were performed for SAL1 (K-feldspar, plagioclase).

Anomalous fading is often considered to ubiquitously cause systematic underestimation of IRSL ages (e.g., ?). However, it has been shown that IRSL emission centred at 410 nm (used in our study) is less affected by fading than UV emissions (?). In particular for the Alps several studies have shown that IRSL ages agree well with independent age control (???). Storage tests used for correcting the signal loss have recently shown to yield IRSL ages that are overestimating independent age control (Gaar and Preusser, 2012; Lowick et al., 2012). Furthermore, it has been shown that the fading rate is probably temperature dependent (?) and ? did not observe fading in their samples from Antarctica. Considering all the above, we refrained from carrying out time-consuming storage tests, especially since it would have been very challenging to simulate the permafrost environment of our samples.

4.6. Analyses of luminescence data

The adequacy of detected luminescence signals for further analyses was evaluated based on their signal intensities above background (shine down curves) and dose-signal relation (growth curves) using the software ANALYST 3.24 (Duller, 2007). The distribution of equivalent doses for each sample is then analyzed using the R software and the R package Luminescence (?) in order to assess the degree of differential bleaching and presence of distinct signal populations.
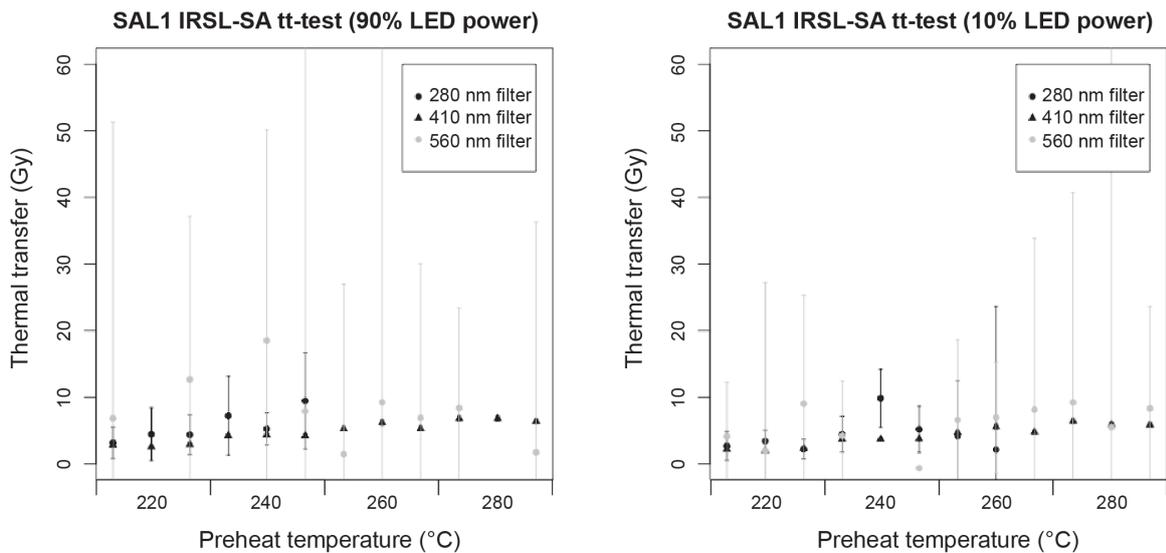

Figure 5: Thermal transfer test for SAL1 K-feldspars comparing three different parameters: preheat temperature (220 °C, 240 °C, 260 °C and 280 °C), optical filters (280 nm, 410 nm, 560 nm) and LED power (90 % and 10 %).

For well-bleached samples, a normal distribution of equivalent doses is expected, with standard deviations corresponding to uncertainties in individual doses and in dose rates. The palaeodose calculation based on the arithmetic mean or using the central age model (CAM; Galbraith et al. 1999) is sufficient. Non-normal distributions and higher standard deviations indicate differential bleaching and hence, require statistical modelling to determine the palaeodose that represents the true burial time of the well-bleached grains (e.g., Olley et al., 1998; Bailey and Arnold, 2006). The minimum age model (MAM) is designed to determine the palaeodose from skewed dose distributions assuming values from well-bleached grains for the lower portion of the distribution (Galbraith et al., 1999). However, the MAM is very sensitive to the lowermost equivalent doses. In the case of sediment mixing with younger grains the use of the MAM might be problematic. For rock glaciers, the grain input processes with differential bleaching and the potential of transport-related sediment mixing suggests that the dose distributions may be composed of several distinct populations. Accordingly, the finite mixture model (FMM; Galbraith and Green 1990) is preferred to determine the dominant population of the sample.

The overdispersion constitutes the essential input parameter for both, the MAM and the FMM. We have no appropriate material (e.g., well-bleached aeolian sand from the study area) to assess the overdispersion of our samples independently. Arnold et al. (2007) and Arnold and Roberts (2009) report values between 0.1 and 0.4 for fluvial deposits from different geographical regions. Accordingly, we tested the effect of using different overdispersion values (0.05 - 0.50) on the performance of the FMM (details are

given in the supplementary material). Due to the overall low variations in FMM results with changes in overdispersion, a value of 0.3 seems to be a reasonable approximation for our samples, which also represents the value found for samples from the Swiss lowlands (Gaar and Preusser, 2012).

5. Results

5.1. Signal properties of quartz OSL

In general, the analyzed material often shows problematic luminescence properties and the low intensities often hardly allow separating the luminescence signal from the background noise. The very few equivalent doses (Tab. 3) of SUV1 (n = 3), SUV2 (n = 1), SUV4 (n = 3), GiG1 (n = 5), and GiG2 (n = 2) that could reliably be determined, provide only limited information about the dose distribution. For such samples, single grain measurements are not adequate enough to allow for the identification of distinct equivalent dose populations and the degree of bleaching. Corresponding dose-response curves from Suvretta and Gianda Grischa show a variable correlation of the OSL signal and applied laboratory dose (Fig. 6; top and middle). Poor recycling ratios and pronounced sensitivity changes and recuperation indicate poor luminescence properties of the measured material. Much brighter signals reveal higher luminescence sensitivities and low errors in equivalent dose estimation for several grains from Suvretta and most grains from Salteras (Fig. 6; bottom). The high uncertainties in recovering applied laboratory doses indicate material-inherent uncertainties that affect the reproducibility of OSL signals. Recovered doses deviate from
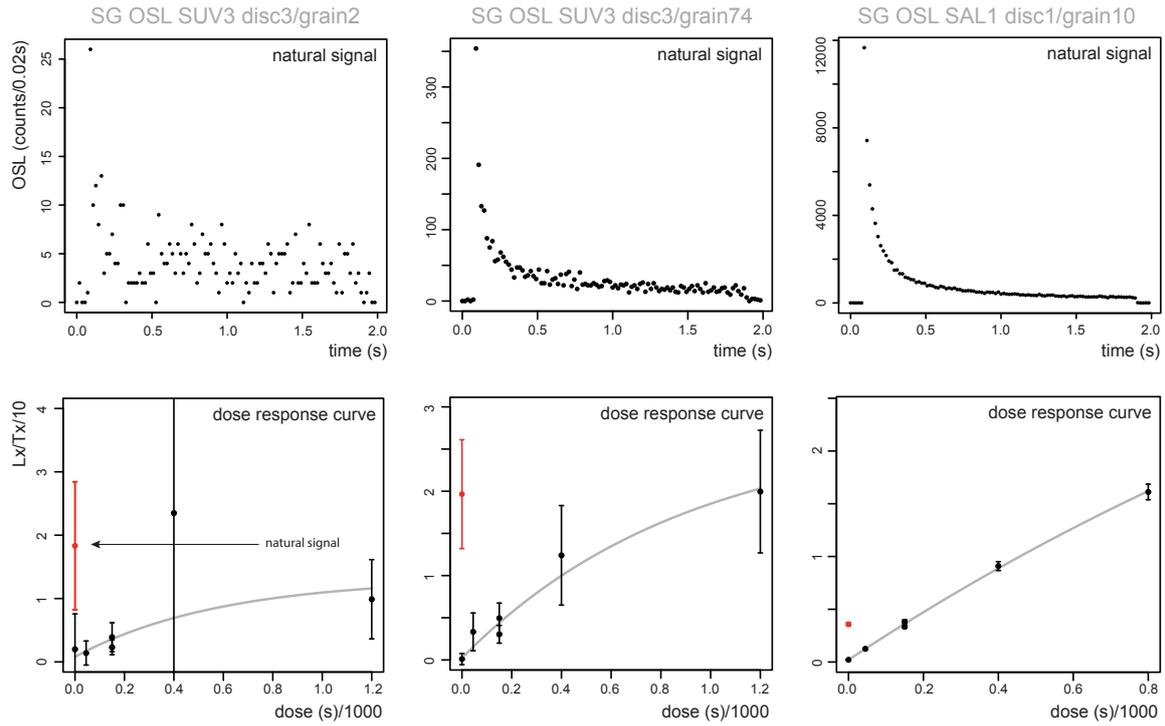

Figure 6: OSL single grain (SG) shine down (left) and dose response curves (right) for samples SAL1 disc1 grain 10, SUV3 disc3 grain 2 and 28.
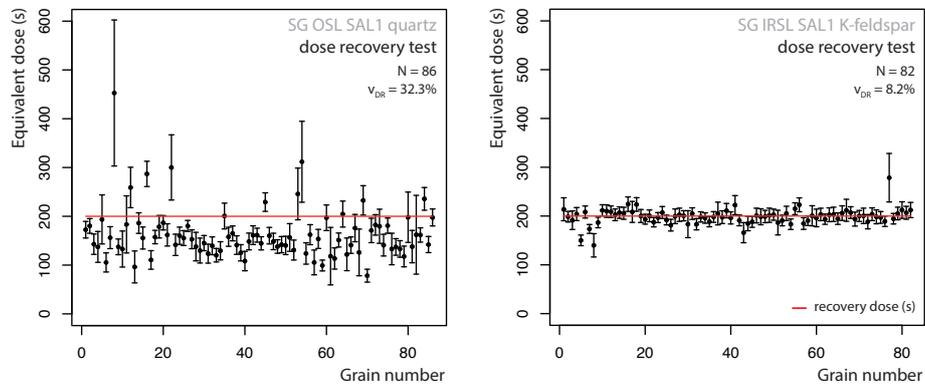

Figure 7: Results from dose recovery tests for single grains (OSL and IRSL) of the rock glacier Salteras. The quartz grains (left) show a clear trend to underestimate the recovery dose (applied dose: 200 s or 36.4 Gy). In the case of K-Feldspar (right), a good reproducibility of the luminescence signals can be estimated, as indicated by the low coefficient of variation v_{DR}. N = number of grains.

the applied dose by more than 30 % in both, multiple-grain aliquot (SAL1) and single grain (SAL1) measurements. The latter tends to underestimate the recovery dose (Fig. 7a).

5.2. Signal properties of feldspar IRSL

Luminescence signals of IRSL single grain measurements show generally higher intensities for K-feldspar com-pared to plagioclase (Fig. 8). More grains reveal initial IRSL signals above the generally elevated background noise of 500 - 1000 counts per 0.01 s. Dose-response curves from the majority of those grains suggest a reliable dose-signal correlation. Recycling ratios close to unity and low recu-peration allow for an improved curve fitting. Dose recovery tests for K-feldspar reproduce the applied laboratory dose with a variation (v_{DR}) of 8.1 % for SAL1 (Fig. 7b). In the
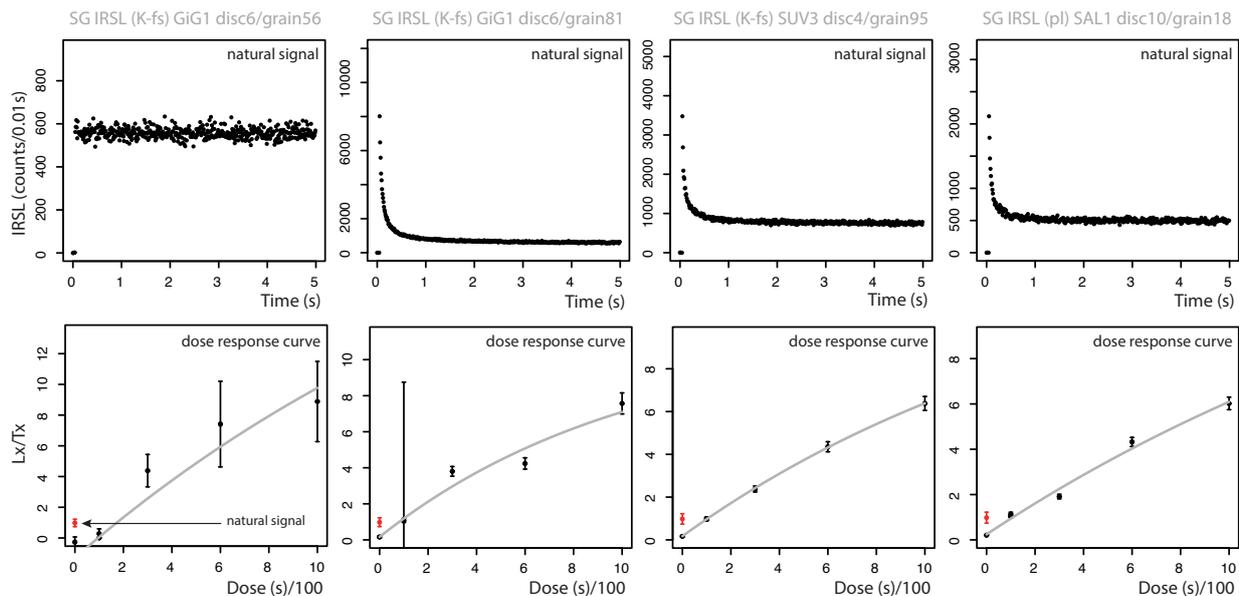

Figure 8: Single grain IRSL shine down curve and dose response curve for K-Feldspar of sample GiG1 and SUV3 and for Plagioclase of sample SAL1.

case of plagioclases (SAL1), the overestimation of the applied laboratory dose resulted also in a high v_{DR} ($\sim 85\%$). The poor reproducibility complicates the interpretation of equivalent doses. Only few equivalent doses could be determined from measured plagioclase grains (SAL1, SUV4). Low signal intensities and large uncertainties in growth curve fitting indicate mostly poor luminescence properties.

5.3. Analyses of equivalent dose distributions

The generally large scatter of equivalence doses (Figs. 9 - 11) implies a heterogeneous composition of the distributions, caused by insufficient bleaching and/or resulting from factors connected to the sediment dynamics within the rock glaciers. Hence, further statistical treatment is needed to infer palaeodoses representing the true age of incorporation. A major problem in our study is the fact that in several cases the luminescence properties described above lead to only few determined values per sample along with high uncertainties (Tab. 3). This complicates or even precludes the analyses of the equivalent dose distributions; such limited datasets do not allow drawing conclusions about the bleaching level. We used the arithmetic mean (as a pragmatic solution) in a descriptive sense but did not calculate luminescence ages for these samples.

Only samples where more than 15 equivalent doses could be determined were used for further statistical analyses (Figs. 9 - 11). Well suited in this context is the Salteras sample (SAL1, Fig. 9) for which a large number of K-feldspar single grain ($n = 74$) and quartz single grain (234) equivalent dose values are available. Additionally, we have a sufficient number of multiple-grain quartz measurements (18) for this sample (Tab. 3). For Suvretta

(Fig. 10), only four out of nine different measurements yielded sufficient numbers of equivalent dose vales: SUV1 multiple-grain quartz (18), SUV2 single grain K-feldspar (60), SUV3 single grain quartz (58), and SUV4 single grain K-feldspar (35). For Gianda Grischa (Fig. 11), only GiG2 single grain K-feldspar (43) gave rise to a substantial number of analyzable measurements (Tab. 3). For all of these samples, we observe a broad spread of equivalent dose values, in many cases with relative standard deviations above 100%. The CAM yields overall lower values compared to simply using the arithmetic mean and thus, may be less affected by outliers (Tab. 3). However, the CAM values do not represent the main cluster at the lower end of the dose distribution as indicated by the probability density function (PDF) of most samples (Figs. 9 - 11). The MAM palaeodose calculation tends to underestimate the main data cluster (maximum in PDF). Especially single low values affect MAM calculations, in some cases leading to palaeodose estimation based on only the lowest 1 - 5 values. The FMM enables a robust determination of the dominant population, corresponding to the main data cluster at the lower end of the dose distribution. Using the overdispersion value of 0.3, we determined two to three components in our samples. In all our samples the highest proportion (for most samples >70%) is represented by the lowest component, except for SAL 1 OSL multiple grain analysis with the second as the main component (Tab. 3). In most cases, the main component is accompanied by a secondary component of $\sim 10\%$ to 30%. For a few samples a minor third component of $<10\%$ could be distinguished comprising the highest dose values. Only for SAL 1 multiple grain OSL this
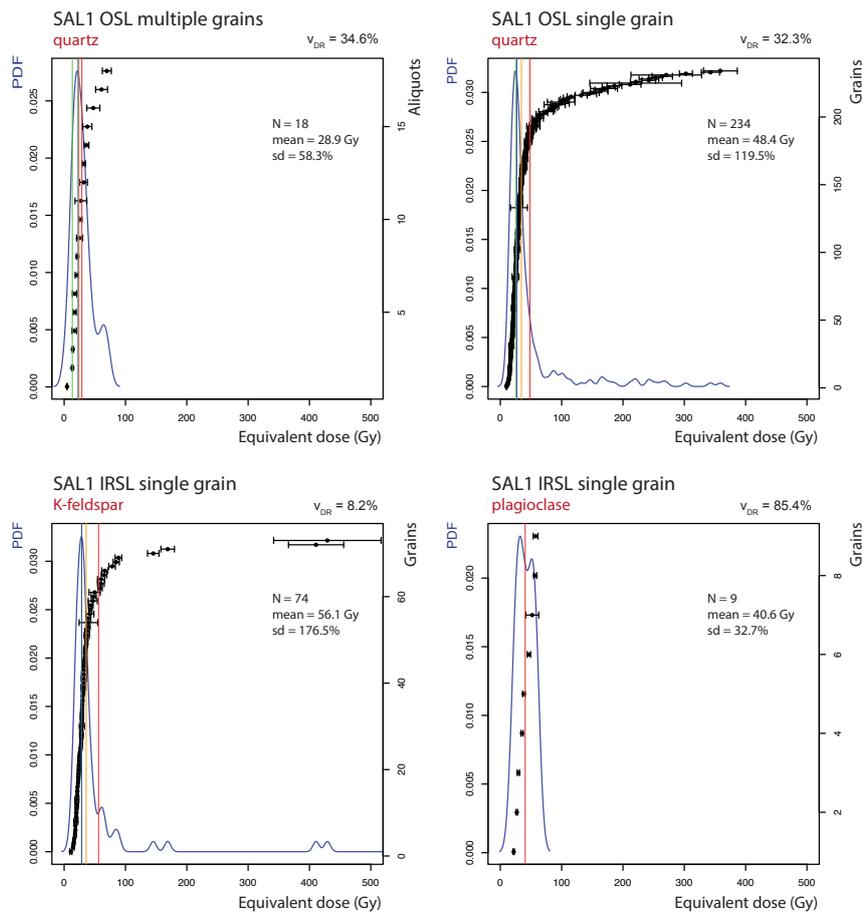

Figure 9: Equivalent dose distributions of the sample from Salteras using different luminescence methods, top: OSL quartz multiple grain (left) and single grain (right), bottom: IRSL K- feldspar (left) and plagioclase (right). Dose distributions are described by the probability density function (PDF). Statistical analyses include the arithmetic mean (red line), the central age model (CAM, orange line), the minimum age model (MAM, green line) and the finite mixture model (FMM, light blue line). v_{DR} = coefficient of variation, N = number of aliquots/grains, sd = standard deviation.

minor component comprises the lowest equivalent doses. Two samples (SUV 2 and GiG 2 single grain IRSL, both K-feldspar) differ from that picture by revealing two prominent components, of which the lower one is slightly dominant ($>50\%$) and the secondary ($<50\%$) indicates a distinct population of higher dose values.

5.4. OSL and IRSL ages

Table 3 summarizes the calculated luminescence ages for samples that allowed statistical analyses based on more than 15 values. All ages represent the main dose population determined by the FMM. The well performing luminescence signals of the Salteras rock glacier revealed ages of (6.4 ± 1.2) kyr and (6.4 ± 0.6) kyr for multiple grain quartz and single grain K-feldspar, respectively. Although the age of (7.7 ± 0.7) kyr for single grain quartz is slightly higher, it confirms the overall consistency of the results from investigated luminescence signals. The less well performing plagioclase single grain signals do not allow for a

robust palaeodose and hence, age calculation. However, detectable equivalent doses and corresponding arithmetic mean are similar to the other luminescence measurements. The consistency of the quartz and K-feldspar ages indicates that anomalous fading is likely not affecting the samples under consideration.

For the rock glacier Suvretta (Tab. 3), we determine consistent ages of (5.2 ± 0.8) kyr (multiple-grain quartz) and (4.8 ± 0.5) kyr (single grain K-feldspar) for the sample SUV2. Unfortunately, the OSL single grain measurements of SUV2 were not successful. All approaches failed for close-by SUV1 apart from three OSL single grain results that indicate significantly higher values. The laterally distant samples SUV3 and SUV4 revealed ages of (3.5 ± 0.5) kyr (single grain quartz) and (3.0 ± 0.6) kyr (single grain K-feldspar), respectively. The OSL quartz and IRSL K-feldspar single grain datasets from SUV3 and SUV4 that consisted only of <15 values cover a comparable dose range like the FMM estimates of the robust datasets (>15 values). IRSL plagioclase measurements for SUV4 were

not able to provide a sufficient dataset.

The sediments taken from the Gianda Grischa rock glacier yielded the poorest luminescence properties. Only for the single grain K-feldspar of sample GiG2, a substantial number of equivalent dose values are available (43), delivering an age of $(3.0 \pm 0.4)\,kyr$. Interestingly, the eight single grain K-feldspar values from sample GiG1 agree with the FMM results of GiG2. In contrast, OSL single grain measurements of both samples yielded only few values with significantly higher doses. The poorly constrained quartz signals prevent reliable age estimation.

6. Discussion

The problematic luminescence properties of quartz and feldspars, especially plagioclase, indicate overall low luminescence sensitivities of the sampled rock glacier material, typical for sediments that underwent no or only few sedimentation cycles (cf. ?. While very low signal intensities are especially encountered with the quartz measurements, also feldspar measurements often show high uncertainties in dose response curves and partly poor reproducibility in the dose recovery tests. In general, the quartz OSL properties of the Salteras sample appear to be far more reliable than those of Suvretta and Gianda Grischa. A similar trend is observed for K-feldspar single grain measurements for Salteras compared to Suvretta and Gianda Grischa. We assume that material intrinsic properties of source rock play an important role for the differences in luminescence behavior of the investigated rock glaciers. Although the rock type is everywhere similar, some minor differences in the mineral assemblage (and mineral structure) might exist (see also Böhlert et al. 2011b,c.

The equivalent doses indicate heterogeneous, in most cases positively skewed distributions that suggest differential bleaching. However, considering the possibility of different grain transport pathways along with sediment mixing, different grain populations may be present. While the MAM tends to underestimate the main signal cluster, palaeodose calculation based on the FMM seems to be more adequate to address both, differential bleaching as well as the possibility of the incorporation of surface-derived grains. For most samples, the main FMM component ($>70\,\%$) represents the prominent signal cluster at the lower range of values that indicates a distinct population of well-bleached grains. Hence, we assume sufficient light exposure of grains during a dominating input process. Interestingly, we observe several rounded grains under the microscope implying the presence of an aeolian component in the sediment matrix. The secondary FMM component of $\sim10\,\%$ to $30\,\%$ comprises higher equivalent dose values accompanied in some cases by an additional third component of $<10\,\%$ for highest values (Tab. 3), but the effects of incomplete bleaching cannot be differentiated from the contribution of sediment mixing. For SUV 2 and GiG 2 single grain IRSL, the prominent secondary FMM component of $40\,\%$ to $47\,\%$ may indicate a distinct input/uptake of an older grain population. Single low values may relate to a minor influence of mixing. The FMM distinguishes only for SAL 1 multiple grain OSL a minor component ($<10\,\%$) from lowest equivalent doses. However, further implications on grain input and transport process for individual dose populations remain unresolved in our dataset.

Dose rate analyses did not reveal any significant disequilibrium in the ^{238}U decay series from direct Rn daughters. More challenging is the estimation of the palaeowater/ice content. The very low in situ contents are associated to the summer conditions during the sampling season and are probably not representative for the entire transfer time. Considering that creeping permafrost requires a high ice content, values close to saturation are more likely representing the average during grain travel. To cope with these overall uncertainties, large uncertainties for water content values have been included in this study. Theoretically, high ice content and ice lenses may have caused an inhomogeneous distribution of dosimeter minerals (quartz, feldspar) and radionuclides (radiation sources controlling signal growth) in the sediment. However, measuring three minerals of different internal dose rates does not reveal systematic effects according to the reduced influence of external microdosimetric variations of K-feldspars compared to plagioclase and quartz. Overall, samples having a sufficient dataset showed a clearly dominant cluster that suggests normal distribution and only a low variation within the main population of assumed well-bleached grains. It appears that the creeping process of rock glacier material results in a more or less constant displacement of grains within the sediment-ice matrix, leading to an averaging effect on dose rates.

The calculated luminescence ages represent the time since grains were incorporated into the rock glacier and transported towards the talus front. Therefore, they provide minimum age of rock glacier formation. Despite difficult material properties, the ages calculated by different approaches (Tab. 3) are consistent for individual sampling sites. However, estimates differ between the different rock glaciers. The longest grain travel times have been determined for Salteras. Compared to Suvretta and Gianda Grischa, this could indicate differences in creeping rates. Additionally, the deviation of results from two laterally distant sites at Suvretta implies that it might be even possible to resolve variations in creeping rates for distinct lateral zones of rock glaciers. To confirm creeping rate differences, additional test are required that address the partly high luminescence variability encountered in dose recovery tests.

All luminescence ages for the currently still active rock glaciers are between 3 kyr and 8 kyr, supported by previous estimates (Haeberli et al., 2003) and in agreement with flow trajectory analyses and photogrammetric approaches that indicate minimum surface ages between 3 kyr and 6 kyr (Kääb et al., 1998; Frauenfelder et al., 2005). This confirms the concept of Holocene rock glaciers developing at millennial time scales as also deduced from weather-

ing rinds, lichenometry and radiocarbon dating (Haeberli et al., 2003). Although derived travel times determine a similar time range as preliminary results of quartz measurements (4 - 8 kyr) for the rock glaciers Murtl, Muragl and La Veduta (Upper Engadine, Switzerland), results cannot be compared in terms of their reliability due to unavailability of measurement details.

However, the OSL based travel times from Salteras, Suvretta and Gianda Grischa indicate differences between the rock glaciers. Recent velocities measured at various sites reveal variations between and within rock glaciers that depend especially on slope, local climate and related ice content as well as temperature (Haeberli et al., 2003; Frauenfelder et al., 2005). Accordingly, the different travel times may simply reflect site-specific variations in flow velocities. To clearly distinguish rock glacier generations from travel times requires further investigations on the respective roles of different flow velocities and activity phases. Overall, the OSL based travel times need to be regarded as minimum ages and indicate that the investigated high Alpine rock glaciers began to evolve during the Early and/or Middle Holocene.

7. Conclusion

This is the first study systematically exploring the potential of luminescence dating of sediments that are imbedded in rock glaciers. In general, poor luminescence properties of both feldspar and, in particular, of quartz were encountered, with only some measurement approaches resulting in robust datasets. Most reliable results were yielded for Salteras, whereas samples from Suvretta and especially Gianda Grischa are highly problematic. Promising is the fact that most datasets showed a clear signal clustering at the lower end of the dose distribution, suggesting sufficient bleaching during a dominant grain input process, likely through aeolian sediment supply to and/or grain retention at the rock glacier surface. The heterogeneous dose distributions also indicate a contribution of incompletely bleached grains, but only limited effects of sediment mixing.

The luminescence ages are consistent at each individual sampling site, but show variations between rock glaciers and may indicate even differences between different parts of the same rock glacier lobe (Suvretta). Again, it should be noted that the ages represent the travel times of grains and hence represent only minimum ages of rock glacier formation. Luminescence ages between 3 kyr and 8 kyr fall within the expected time range determined by other relative and semiquantitative approaches, indicating that rock glaciers started their present phase of activity in the Early/ Middle Holocene. While the derived minimum ages do not further narrow down onset of rock glacier formation, they deliver valuable constraints about grain travel times and, hence, dynamics of rock glacier material. However, several questions about variations in luminescence properties and dose rates of sediments with high ice content have not been investigated here in detail, and need to be addressed in future studies.
