

Special Section:

Southern Ocean and Climate:
Biogeochemical and Physical
Fluxes and Processes

Key Points:

- Hydrographic status update with the first comprehensive CTD survey along the entire FRIS front since 1995
- Strong and stable presence of High Salinity Shelf Water in Ronne Depression over decades
- Dominance of Ronne-sourced Ice Shelf Water in Filchner Trough in 2018 points to intensified sub-FRIS circulation

Abstract The Filchner-Ronne Ice Shelf (FRIS) is characterized by moderate basal melt rates due to the near-freezing waters that dominate the wide southern Weddell Sea continental shelf. We revisited the region in austral summer 2018 with detailed hydrographic and noble gas surveys along FRIS. The FRIS front was characterized by High Salinity Shelf Water (HSSW) in Ronne Depression, Ice Shelf Water (ISW) on its eastern flank, and an inflow of modified Warm Deep Water (mWDW) entering through Central Trough. Filchner Trough was dominated by Ronne HSSW-sourced ISW, likely forced by a recently intensified circulation beneath FRIS due to enhanced sea ice production in the Ronne polynya since 2015. Glacial meltwater fractions and tracer-based water mass dating indicate two separate ISW outflow cores, one hugging the Berkner slope after a two-year travel time, and the other located in the central Filchner Trough following a ~six year-long transit through the FRIS cavity. Historical measurements indicate the presence of two distinct modes, in which water masses in Filchner Trough were dominated by either Ronne HSSW-derived ISW (Ronne-mode) or more locally derived Berkner-HSSW (Berkner-mode). While the dominance of these modes has alternated on interannual time scales, ocean densities in Filchner Trough have remained remarkably stable since the first surveys in 1980. Indeed, geostrophic velocities indicated outflowing ISW-cores along the trough's western flank and onto Berkner Bank, which suggests that Ronne-ISW preconditions Berkner-HSSW production. The negligible density difference between Berkner- and Ronne-mode waters indicates that each contributes cold dense shelf waters to protect FRIS against inflowing mWDW.

Plain Language Summary We visited the largest floating Antarctic ice shelf in the southern Weddell Sea in 2018 with an icebreaker expedition, and measured ocean temperature, salinity, meltwater content, and other parameters in front of the FRIS. We found that the ocean conditions were still dominated by the very cold and dense waters needed to protect the ice shelf from inflowing warm waters from the deep ocean. We compared the 2018 conditions with earlier surveys since the 1980s and concluded that, in spite of climate change and in contrast to other Antarctic regions, the water masses on the southern Weddell Sea shelf remained relatively stable overall. We found that most of the stations we visited near the Filchner Ice Shelf edge were dominated by cold ISW, which forms when water masses interact with the underside of the shelf ice. Our measurements helped improve our understanding regarding the currents and water masses on the southern Weddell Sea continental shelf.

1. Introduction

The Antarctic continent stores the largest amount of freshwater on Earth. However, the Antarctic ice sheets and glaciers are losing mass, leading to a cumulative sea level rise of 14 mm since 1979 (Rignot et al., 2019). Some ice mass loss could be linked to changes in the atmosphere, such as the warming of the Antarctic Peninsula (Vaughan et al., 2003), which triggered the decay of the Larsen ice shelves (Broeke, 2005; Rott et al., 1996). However, the majority of ice mass was lost from glaciers and ice sheets that were exposed to the influence of warm ocean waters (Rignot et al., 2019). Thompson et al. (2018) classify the Antarctic

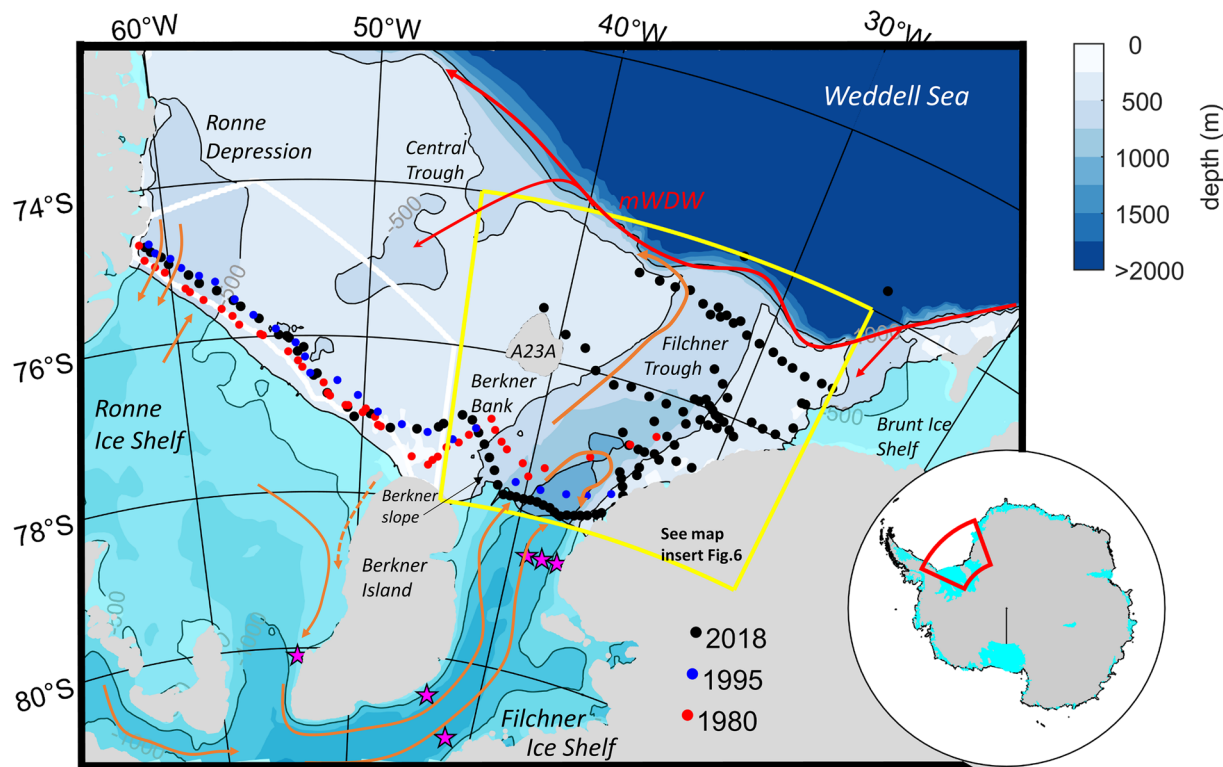

Figure 1. Map of the southern Weddell Sea including CTD stations from 2018 (black), 1995 (blue), and 1980 (red). Magenta stars indicate drill hole moorings mentioned in the text for reference (H2021). Ice Shelves are marked with cyan shading, bathymetry (Schaffer et al., 2016) is shown in blue color contours. The 500 and 1,000 m isobaths are marked with black contours. Bathymetric and geographic features referred to in the text are indicated in the map. The area north of RIS inside the white line marks the region used to quantify sea ice production (Figure 12). The Filchner Trough framed by the yellow lines marks the inset used in Figure 6. The arrows indicate the inflow branches of modified Warm Deep Water (red) and the under-FRIS circulation fueled by the inflow of High Salinity Shelf Water (orange).

marginal seas into “warm”, “fresh”, and “dense” shelves based on their hydrographic properties impacted by the dynamics of the Antarctic Slope Current system and associated frontal dynamics. On “warm” continental shelves such as along the West Antarctic Peninsula or in the Amundsen and Bellingshausen Seas, warm waters of open ocean origin intrude inshore by following the seafloor since there is no strong front separating the shelf from the warm Circumpolar Deep Water (CDW) as is found on the “fresh” shelves surrounding the Antarctic continent. The “dense” continental shelves of the Ross and Weddell Seas are wide and dominated by near-freezing conditions (Nicholls et al., 2009) and characterized by moderate ice shelf basal melt rates (Paolo et al., 2015; Rignot et al., 2019). The Filchner-Ronne Ice Shelf (FRIS), Antarctica’s largest ice shelf by volume, is located south of such a “dense” wide continental shelf in the Weddell Sea. The circulation and oceanographic conditions on this southern Weddell Sea shelf are dominated by a saline water mass named High Salinity Shelf Water (HSSW). HSSW is at surface-freezing temperature ($\sim -1.9^\circ\text{C}$) and forms as a result of sea ice production on the continental shelf and in coastal polynyas, in particular in the southwestern Weddell Sea off Ronne Ice Shelf (RIS, Haid & Timmermann, 2013). HSSW has salinities of 34.60–34.85 and contributes to the dense shelf waters or directly flows off the shelf across the continental slope and contributes to the formation of Weddell Sea Deep and Bottom Waters (Gordon et al., 1993; Orsi et al., 1999), which are precursors of Antarctic Bottom Water (AABW). Data from moorings at the ice shelf front (Nicholls et al., 2004), sub-ice shelf moorings (Nicholls et al., 2001), and model studies (Timmermann et al., 2012) indicate that HSSW enters the cavity below FRIS following the bathymetry in Ronne Depression and drives an ice shelf-wide thermohaline circulation (Figure 1). En route through the cavity, HSSW may encounter greater water pressures that lower the in situ freezing point to match its own surface-freezing temperature, thereby causing melting at the base of the ice shelf (model-derived average of 0.34 m yr^{-1} at FRIS; Timmermann et al., 2012). The resulting modified water mass is colder and fresher and hence more

buoyant and is referred to as Ice Shelf Water (ISW). ISW is characterized by below-surface freezing temperatures ($<-1.9^{\circ}\text{C}$) and leaves the FRIS cavity via the Filchner Trough (Nicholls et al., 2009).

These cold and dense waters prevent a large-scale inflow of Warm Deep Water (WDW), the Weddell Sea's derivative of CDW, which occupies the intermediate layer (200–1,200 m) of the Weddell Sea (Daae et al., 2020). This is not the case along the narrow continental shelf off Dronning Maud Land, where WDW mixes with the colder and fresher Eastern Shelf Water to result in modified (m)WDW, which seasonally penetrates the southern Weddell Sea through troughs intersecting the continental shelf (Ryan et al., 2017). The seasonal flow of modified Warm Deep Water (mWDW) onto the shallower shelf is regulated by the Antarctic Slope Front, which responds to changes in the wind field and stratification (Hattermann, 2018) and controls cross-frontal exchange through mesoscale eddies and instabilities (Nøst et al., 2011; Stewart & Thompson, 2015; Stewart et al., 2018). On FRIS, however, the impact of mWDW is presently limited by the cold, dense waters that occupy the Filchner Trough, though model studies suggest that a freshening of the shelf water masses under warmer atmospheric conditions may lead to enhanced warm water inflow and dramatic ice shelf melting by the end of this century (Daae et al., 2020; Hellmer et al., 2012, 2017). MWDW is a persistently observed water mass at the RIS front, west of Berkner Bank (Foldvik et al., 2001; Gammelsrød et al., 1994), and also has been observed at the Filchner Ice Shelf (FIS) front (Darelius et al., 2016). Recent moored temperature records indicate considerable interannual variability of mWDW-presence in Filchner Trough (Ryan et al., 2020). At present, this does not appear to significantly contribute to FRIS mass loss, as mWDW resides above the depth of the ice shelf front atop denser waters that occupy the Filchner Trough. However, future melt rates will crucially depend on the evolution of the dense water masses and circulation on the southern Weddell Sea continental shelf.

Prior to 2017, the hydrography at FIS front was dominated by water masses that were formed on Berkner Bank (Figure 1), referred to as Berkner-HSSW (Akhoudas et al., 2020), and seasonal outflows of ISW along the western flank of the trough (Darelius & Sallée, 2018). However, temperature and salinity records from moorings underneath FRIS have shown an intensification of the Ronne-HSSW driven cavity circulation in response to increased sea ice formation in the Ronne Polynya since 2015. This resulted in a decline in Berkner-HSSW and an increase in Ronne HSSW-derived ISW in the Filchner Trough in mid-2017 (Hattermann et al., 2021, from here on referred to as H2021). Shortly thereafter, in austral summer 2018, an *RV Polarstern*-expedition (PS111) was able to access both FIS and RIS fronts during extended polynya events and undertake a detailed hydrographic survey.

In this paper, we present a 2018 hydrographic status update of the FRIS front and Filchner Trough, and contrast our findings with those from earlier expeditions. Further, we investigate the variability of circulation regimes underneath FRIS as inferred from observed ocean conditions in Filchner Trough. Specifically, we discuss two contrasting circulation modes that are immediately connected to HSSW production north of RIS and on Berkner Bank, referred to as Ronne- and Berkner-modes. We examine these modes in a historical context and finally discuss the impact of changes in forcing parameters on the regional and large-scale ocean circulation.

2. Materials and Methods

2.1. Hydrographic Data

Hydrographic measurements were carried out onboard the German research icebreaker *RV Polarstern* (Alfred-Wegener-Institut Helmholtz-Zentrum für Polar-und Meeresforschung, 2017) during the PS111-expedition to the southern Weddell Sea (Figure 1) from January 12 to March 14, 2018 from Cape Town, South Africa, to Punta Arenas, Chile. Temperature and salinity profiles during PS111 (Janout et al., 2019) were collected with a Seabird 911+ CTD (Conductivity-Temperature-Depth) recorder attached to a water sampling carousel. The raw data were processed with the Seabird processing software and quality controlled thereafter. Pre- and post-cruise calibrations of the conductivity and temperature sensors were performed by the manufacturer. Finally, the salinity values were corrected with salinity measurements from water samples, which were measured with an Optimare Precision Salinometer. The final accuracies of the CTD data are estimated as 0.0005°C and 0.002 for temperature and salinity, respectively. Dissolved oxygen measurements were collected with an oxygen sensor attached to the CTD. The sensor was carefully calibrated

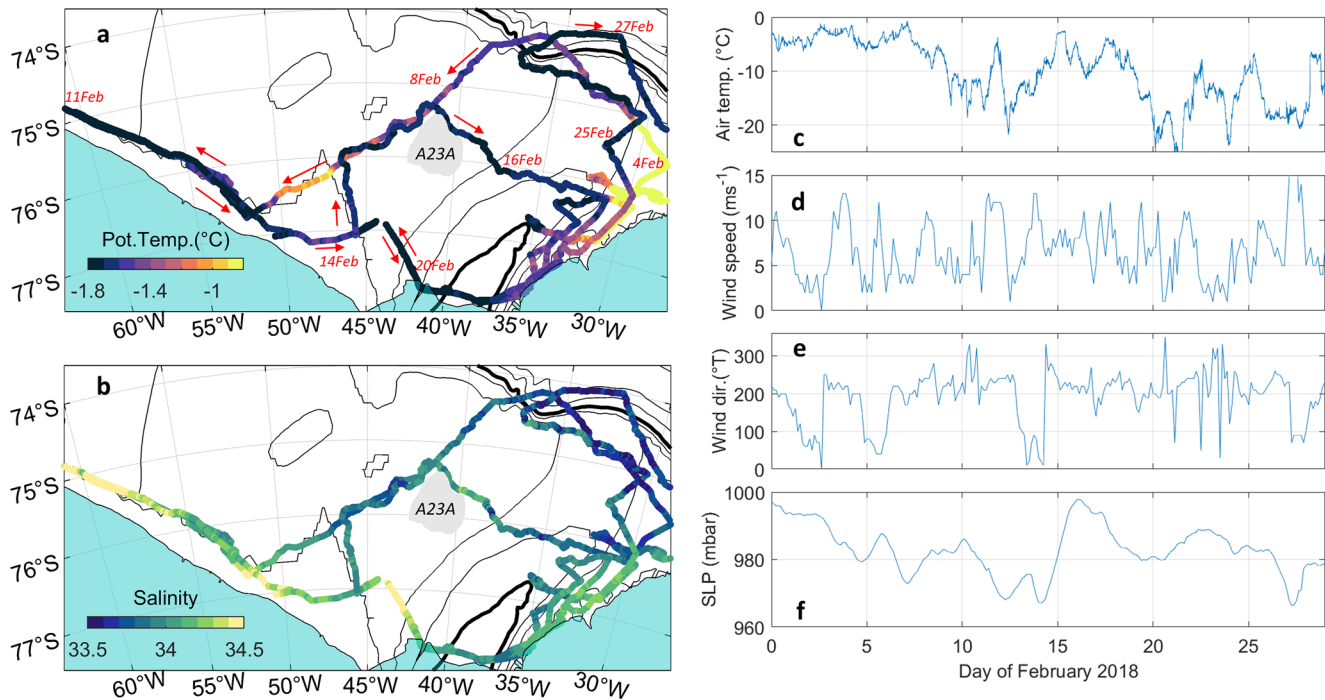

Figure 2. Along-track (a) temperature (°C) and (b) salinity measured by the ship's thermosalinograph at 11 m water depth, (c) air temperature (°C), (d) wind speed (m s^{-1}) and (e) direction (°T); (f) sea level pressure (mbar) measured locally by RV Polarstern's weather system displayed against the day of February. Arrows indicating travel direction and occupation dates in panel (a) are provided for better orientation. Cyan shading in (a) and (b) indicate ice sheets and ice shelves. Bathymetry contours in black mark every 500 m; the 1,000 m isobath is marked by the bold line.

throughout the expedition by measuring the oxygen content of water samples using the Winkler titration method. Along-track oceanographic and meteorological parameters were measured with RV Polarstern's fixed installed underway measurement system. Temperature and conductivity at 11 m (Figures 2a and 2b) were measured with a thermosalinograph SBE21 (Schröder & Rohardt, 2018) with accuracies of 0.001°C and 0.001 S/m. Air temperature, wind speed and direction, and atmospheric pressure (Figures 2c–2f) were measured with Polarstern's weather system (Schmithüsen, 2020).

Geostrophic velocities were computed from the density structure measured via CTD stations along FRIS assuming a level-of-no-motion at 200 m as this is the minimum thickness of the edge along FRIS (Schaffer et al., 2016). In order to distinguish between ISW sourced from either Ronne- or Berkner-HSSW, we defined the respective source water salinities by finding the crossing point of the ISW Gade line (Gade, 1979) with the surface freezing temperature line. This method assumes water mass transformation along characteristic lines in temperature-salinity-space in the absence of other mixing end members. We neglected the effect of heat conduction at the ice shelf-ocean interface and used a slope of 2.4 K/psu of the Gade line, resulting from $\Delta T/\Delta S = L/(S_0 c_p)$, where the latent heat of ice is $L = 3.34 \times 10^5 \text{ J kg}^{-1}$, the specific heat capacity of seawater $c_p = 4,186 \text{ J kg}^{-1} \text{ K}^{-1}$, and S_0 is the seawater salinity.

We revisited earlier hydrographic stations to view the 2018-observations in a decadal context and to understand the variability in hydrographic properties and tracers along the FRIS front. Prior to 2018, the most comprehensive surveys along FRIS took place in 1980 (early January to mid-February) aboard the RV Polarstern (Gammelsrød & Slotsvik, 1981) and in 1995 (late January to early March) aboard RV Polarstern (Schröder, 2010). We use CTD stations from both earlier surveys as well as tracer data from 1995. Similar to PS111, both historic surveys entered the Ronne ice front region through polynyas, and CTD stations were approximately sampled at the same relative distance from the shelf ice. For an interannual comparison of source water salinities in Filchner Trough, we further investigated historical CTD stations collected between 1973 and 2018 (see Carmack & Foster, 1975; Driemel et al., 2017; Foldvik et al., 1985 for historic data details).

2.2. Glacial Basal Melt Water (GBMW) From Oceanic Noble Gas Measurements

Water samples from the CTD-rosette-system were collected in gas tight copper tubes and subsequently analyzed for noble gas content with the IUP Bremen mass spectrometer (Sültenfuß et al., 2009). Oceanic measurements of the low-solubility and stable noble gases helium (He) and neon (Ne) provide a useful tool to identify and quantify GBMW (e.g., Hohmann et al., 2002; Huhn et al., 2008, 2018; Rhein et al., 2018; Schlosser, 1986). Atmospheric air with a constant composition of these noble gases is trapped in the ice matrix during formation of the meteoric ice. Due to the enhanced hydrostatic pressure at the ice shelf base, these gases are completely dissolved in the water when the ice melts. This leads to a He concentration of 25.7 nmol/kg and a Ne concentration of 90.1 nmol/kg in pure GBMW (Loose & Jenkins, 2014). GBMW is detectable at fractions of <0.05% based on an accuracy of <0.5% for He measurements performed at the IUP Bremen. Some GBMW may be enriched with crustal He (i.e., the isotope ^4He) from α -decay of uranium, thorium, and their daughter products in the bedrock beneath an ice sheet. On geological timescales, the crustal He accumulates in the overlying ice up to 300 m above the bedrock (Beaird et al., 2015; Suess & Wänke, 1963). A He surplus of 4.5 ± 0.5 times that of GBMW has been observed in deep ice near to bedrock. Some He (mainly primordial ^3He) is released by mid-ocean ridges to the ocean's interior by hydrothermal activity (Clarke et al., 1969; Well et al., 2003), increasing the $^3\text{He}/^4\text{He}$ ratio (expressed as $\delta^3\text{He}$ in‰) in the water vs. the equilibrium ratio. We used the He and Ne concentrations and the method from Rhein et al. (2018) to calculate the fractions of GBMW. First, we estimated the mean mixed layer supersaturation from noble gas stations at a distance from the ice shelf front (to avoid bias from upwelled GBMW into the mixed layer) and subtracted this value from the measured values. Then, we subtracted the equilibrium value $\text{He}_{\text{EQ}}(\theta, S)$ and $\text{Ne}_{\text{EQ}}(\theta, S)$ (for each data point as a function of the local potential temperature θ and salinity S using the solubility function from Weiss, 1971) from the observed values and attributed the remainder to pure GBMW. In this paper, we show GBMW calculated from Ne to exclude any bias from additional crustal He.

Additionally, we analyzed 335 seawater samples for the transient tracers chlorofluorocarbon CFC-12 and sulfur hexafluoride SF_6 . These anthropogenic trace gases have increased in the atmosphere due to rising human production and enter the ocean via gas exchange at the ocean surface. Hence, they allow us to determine transit time scales of oceanic transport (Huhn et al., 2013; Smethie & Fine, 2001; Waugh et al., 2003). Samples were filled from the CTD-rosette-system into glass ampoules avoiding atmospheric contact. The ampoules were flame-sealed after a tracer-free headspace of purified nitrogen was applied. Later, at IUP Bremen, the samples were analyzed by purge and trap pre-treatment followed by gas chromatographic (GC) separation on a capillary column and electron capture detection (Bulsiewicz et al., 1998). The total error of the measurement was $\pm 2\%$ for CFC-12 and $\pm 5\%$ for SF_6 . Here, we show the partial pressure of these trace gases in the samples instead of concentration to account for the solubility of these gases under different temperatures and salinities (Bullister et al., 2002; Warner & Weiss, 1985).

Water mass ages (i.e., the time lag between the last contact with the atmosphere and time of observation) were determined from the ratio of $\text{SF}_6/\text{CFC-12}$. The ratio excludes the effect of mixing with old (tracer-free) water and possible saturation dis-equilibria during formation (assuming identical equilibration fractions for both tracers). First, we calculated the partial pressure of these gases in each sample from the concentrations, temperature, and salinity using the solubility functions from Bullister et al. (2002) and Warner and Weiss (1985). Second, we compared the partial pressure ratio in each sample with the known atmospheric ratio time history (Bullister, 2017), and determined the year of equilibration with the atmosphere and finally the age as the time lag between year of observation and formation.

2.3. Ronne Sea Ice Production Estimates

The highest sea ice production rates in the southern Weddell Sea are found in coastal polynyas, areas characterized by open water, thin ice, and low sea ice concentration (Paul et al., 2015). Coastal polynyas form all along FRIS, driven by offshore winds and tides. We used results from a simulation with the global Finite Element Sea ice–ice shelf–Ocean Model (FESOM, Timmermann et al., 2012; Wang et al., 2014) to derive sea ice production estimates in polynyas associated to the Ronne sector (white framed area in Figure 1) in the southern Weddell Sea (1985–2017). The model was run on a grid with horizontal resolution that varied between 3 km under the ice shelves, 6–7 km along Ronne Ice Front, and up to 25 km north of the Weddell Sea continental shelf. We used a hybrid vertical coordinate system with 36 layers. Ice shelf draft,

cavity geometry, and global ocean bathymetry were prepared from the 1 min version of RTopo-2 (Schaffer et al., 2016). This model was initialized in 1979 from temperature (Locarnini et al., 2010) and salinity data (Antonov et al., 2010) derived from the World Ocean Atlas 2009, and run until the end of 2017 using atmospheric forcing from the ERA-Interim reanalysis (Dee et al., 2011) on a 75 km horizontal grid, with 6-hourly air and dew point temperatures (both at 2 m altitude), 10 m wind fields, as well as 12-hourly average shortwave and longwave radiation, precipitation and evaporation values. We calculated cumulative annual ice production within polynyas in the Ronne sector (Figure 1) from the daily data. Only positive sea ice production rates were taken into account and nodes with sea ice concentration <70% or thickness <20 cm were considered to be polynyas.

3. Results

3.1. Surface Hydrography on the Southern Weddell Sea Shelf in February 2018

In February 2018 the near-surface (11 m) southern Weddell Sea shelf water was characterized by predominantly cold and saline conditions, with average along-track temperature and salinity of -1.6°C and 33.9°C , respectively (Figure 2). During the sampling period, heavy sea ice conditions in the southern Weddell Sea inhibited access to the slope region west of $\sim 36^{\circ}\text{W}$. However, extensive open water regions were found in a large polynya along the eastern Filchner Trough and near the shelf break in the northeast, where maximum temperatures of -0.8°C were measured in early February. The warm temperatures then vanished during the second visit to the region in late February, with the sea ice cover rapidly closing under freezing air temperatures (Figure 2c) during the transition to winter conditions. Southwest of the grounded iceberg A23 A (Figure 2), an extended region with decreased sea ice concentration, which had been apparent since November 2017 (not shown), developed into open water by February 2018. This region (45°W – 50°W) is within the mWDW-inflow region along Central Trough that will be discussed in more detail later, and showed above-freezing surface waters of -1.3°C during our transit on February 10, 2018 (Figure 2a). Tides are considerable on the southwest Weddell Sea shelf (Makinson, 2002) and likely cause upward heat fluxes of the mWDW to the surface, which may contribute to the local reduction in sea ice concentration there. All other regions along the cruise-track featured near-freezing surface waters. In particular, the westernmost track along RIS was carried out along a narrow (~ 5 – 10 km) polynya caused by southerly winds before and during our visit in early-to-mid February 2018 (Figures 2d and 2e), which led to active sea ice formation with minimum air temperatures reaching below -20°C (Figure 2c) during the time of our observations. Surface salinities showed considerable gradients from the northeast to the southwest (Figure 2b). The northeast is influenced by local and advected meltwater with minimum salinities of 33.5 and slightly higher values of up to 34.0 toward the FIS edge. Maximum surface salinities of 34.5 were found in front of RIS.

3.2. Hydrographic Conditions Along the FRIS Edge and in Filchner Trough in 2018

The hydrography along the RIS front in austral summer 2018 was dominated by HSSW with salinities of up to 34.84 in the deepest part of Ronne Depression (Figures 3a and 3b). The overlying water column was salinity-stratified with temperatures near the freezing point from surface to bottom. Thermohaline measurements indicated the presence of an ISW core located on the eastern flank of Ronne Depression carrying temperatures of -2.1°C . Furthermore, the ISW sampled was found to possess high levels of ΔHe and ΔNe (not shown) and was thus enriched in GBMW (0.8%, Figure 4a). Geostrophic velocities suggested a 1 – 5 cm s^{-1} northward flow (Figure 5). Another previously identified outflow branch (Nicholls et al., 2004) appeared on the western edge of this transect at 60°W , although without super-cooled waters and only slightly enriched in GBMW (0.5%, Figure 4a). The hydrography further east near Berkner Bank around 52°W was characterized by the inflow of -1.5°C mWDW that was guided from the shelf break toward the ice shelf front along Central Trough (Figure 1). The mWDW present at the continental slope was significantly warmer than the -1.5°C waters observed at the ice shelf edge (i.e., the maximum temperature in transect number four in Figure 6 was -0.2°C), which suggests that a substantial amount of mWDW-heat was lost during the ~ 500 km long route across the southern Weddell Sea shelf. The inflow had a geostrophic velocity core of ~ 5 cm s^{-1} and was characterized by the highest $\delta^3\text{He}$ -rates observed in the transect (not shown). $\delta^3\text{He}$ quantifies the contribution of mantle Helium from mid-ocean ridges in a water mass such as CDW and its derivatives (Ryan et al., 2016; Well et al., 2003), thus underlining the deep-water source of the mWDW.

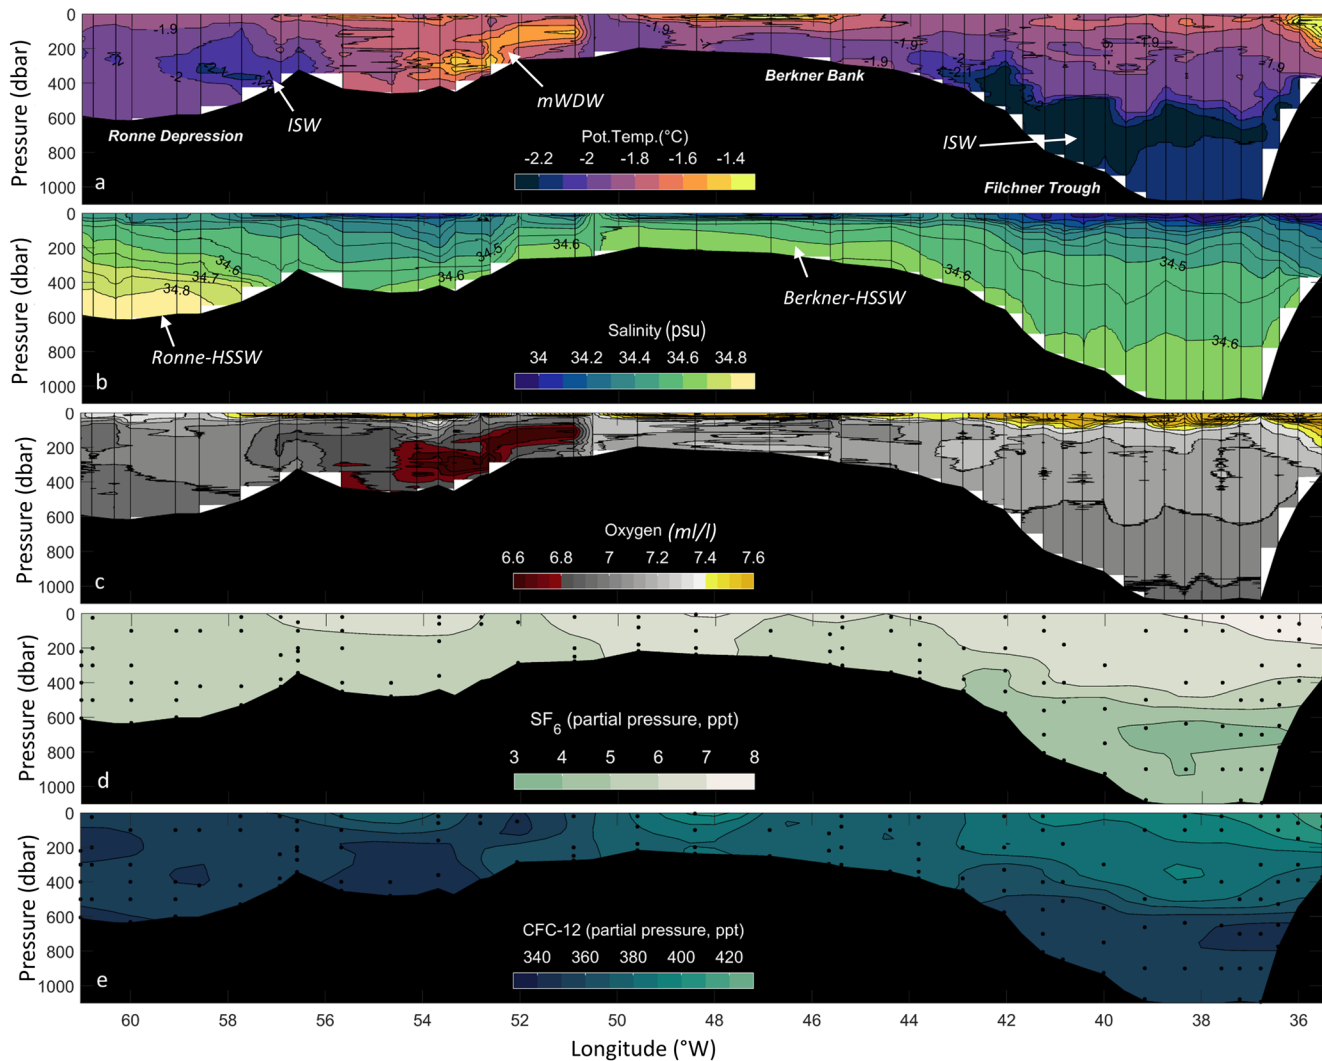

Figure 3. Properties along the FRIS front in austral summer 2018: (a) potential temperature ($^{\circ}\text{C}$), (b) salinity, (c) oxygen (ml l^{-1}), (d) SF_6 (ppt), and (e) CFC-12 (ppt). Station locations can be found in Figure 1 and are indicated by vertical black lines in panels (a–c) and by black dots in panels (d–e). Objective mapping was used to interpolate between stations in panels (d and e).

Filchner Trough was strongly dominated by ISW extending across its entire width, with a minimum temperature of $<-2.2^{\circ}\text{C}$ (Figure 3a) leaning against and encroaching up the western flank between depths of 300–900 m. The ISW core contained salinities of 34.55–34.60 and agreed with a well-defined outflow core of $1\text{--}5\text{ cm s}^{-1}$ (Figure 5). Noble gas tracers were highly enriched in the western flank’s ISW-outflow, presenting the highest ΔHe and ΔNe values (not shown) found along the FRIS front, containing as much as 1% GMBW (Figure 4a). Another outflow is seen against the eastern flank (Darelius et al., 2014a), which has been hypothesized to be associated with eastward propagation of the ISW plume parallel to the FIS front due to the step induced by the ice shelf edge and related vorticity constraints (Darelius & Sallée, 2018). However, drill hole moorings roughly 60 km south of the FIS edge show the existence of a northward flowing branch of this water mass along the eastern flank of the cavity (H2021). The upward-sloping isohalines against the eastern flank (Figure 3b) and resulting geostrophic velocities (Figure 5) suggest an inflowing undercurrent below the outflow at around 600 m, which is consistent with recirculating ISW and Berkner-HSSW in Filchner Trough (Carmack & Foster, 1975). The surface layer showed warmer ($\sim-1.3^{\circ}\text{C}$) waters extending from the eastern corner of the transect, along with lower salinities (<34.0). These waters result from summertime warming and sea ice melt, possibly fed by the coastal current that enters the area from Brunt Ice Shelf (Nicholls et al., 2009). In this region, the oxygen content was the highest (7.6 ml l^{-1}) along the FRIS

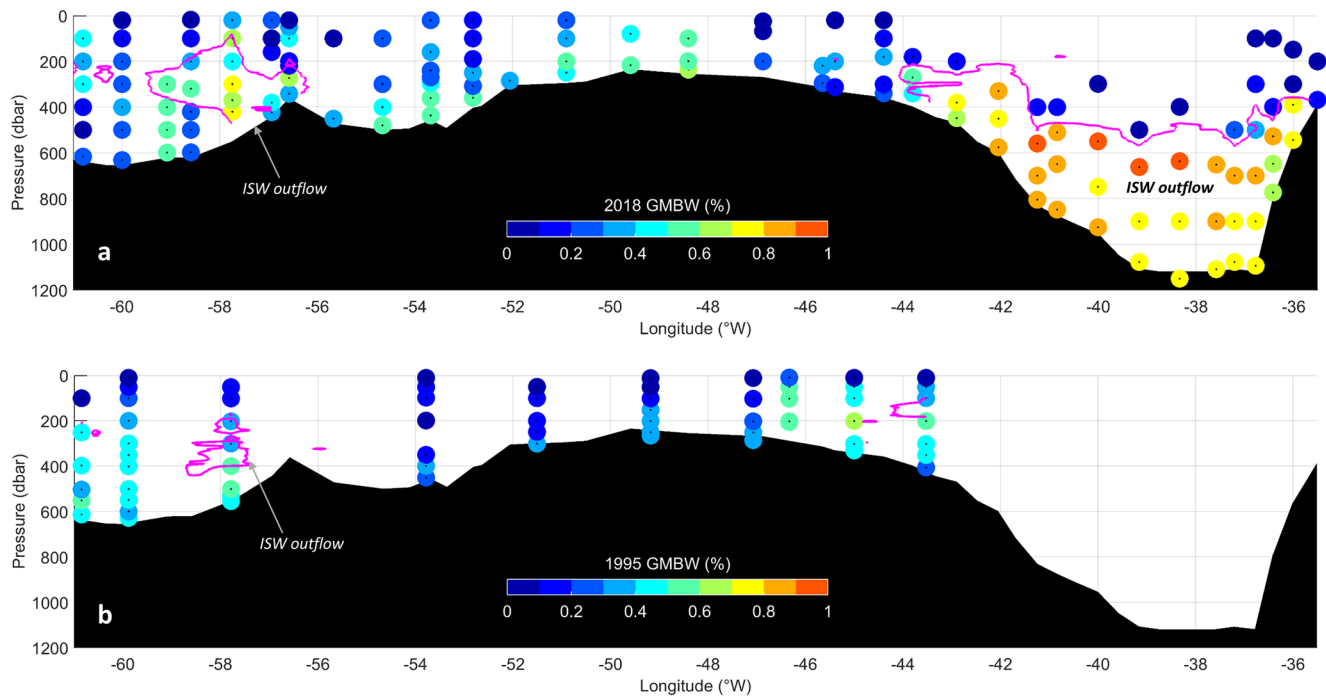

Figure 4. Glacial basal melt water fractions (%) along FRIS shown by colored dots at the sample location and depth in (a) 2018 and (b) 1995. Magenta contours in either panel marks the -2.0°C -isotherm as an indicator for ISW outflow based on the CTD transects in these years.

front (Figure 3c), and indicates a recent interaction of these waters with the atmosphere. This is further supported by the highest CFC-12 and SF₆-values found throughout the transect (Figures 3d and 3e). The lowest oxygen content of 6.6 ml l^{-1} was found in the mWDW-inflow (Figure 3c, 50°W – 55°W), which reflects the greater age of these deep and poorly ventilated waters (Hoppema et al., 1997). HSSW-oxygen content was slightly (by $\sim 0.1 \text{ ml l}^{-1}$) lower than that of ISW, which is explained by the oxygen enrichment of the ISW during ice shelf melting due to air trapped inside the ice. Since, however, the air trapped in the shelf ice was of a pre-industrial age, it did not include any anthropogenic tracers, thus explaining the low trace gas levels in the ISW (Figures 3d and 3e). Overall, the hydrography, along with oxygen and noble gas tracers, confirmed the previously established circulation scheme at the FRIS front (Nicholls & Østerhus, 2004). The dominant characteristics included the HSSW inflow at 59°W – 60°W (although the density structure did not suggest such inflow at the time of survey) and the ISW outflow centered at 58°W at RIS, and the more significant ISW presence with well-defined outflow cores at FIS including the highest GBMW fractions of 1.0%.

Additional temperature and salinity transects across the northern parts of Filchner Trough and sill indicated the northward extent of the ISW upon exiting from beneath the ice shelf (Figure 6). While the coldest

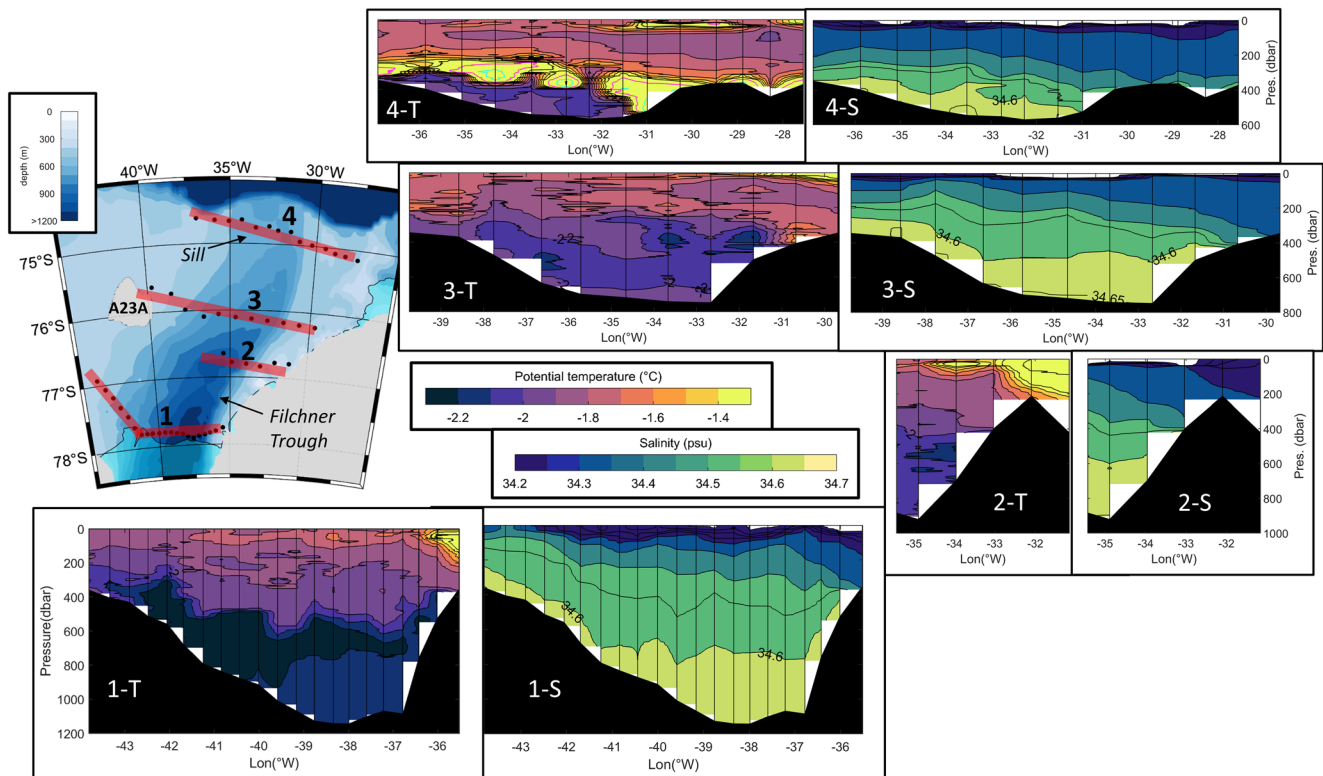

Figure 6. Filchner Trough CTD transects. The map is a zoom into the Filchner Trough region framed by the yellow box in the overview map in Figure 1 and shows the location of four transects. Stations are indicated by black dots on the map, highlighted by red lines. Bathymetry is displayed in color with 100 m increments as shown by the colorbar. Potential temperature (left) and salinity (right) are shown for each transect. Station locations are indicated by vertical black lines. The number on each panel refers to the numbered transects in the map. Note that the panels are scaled according to degrees longitude for a better comparison. The seafloor bathymetry was drawn based on the depth of each CTD profile, which generally was sampled down to 5–10 m above the seafloor. Separate colormaps for temperature and salinity are displayed by the colorbars in the center of the Figure. Color ranges are identical for all 4 transects. Please note that maximum temperatures in transect 4 exceeded the color-limit capped at -1.3°C . For better readability, the small cross-areas featuring -1.0°C and -0.5°C waters are displayed in magenta and green contours, respectively.

ISW of $<-2.2^{\circ}\text{C}$ dominated at the FIS front (transect 1), the eastern and western slopes of the northern Filchner Trough (transects 2 and 3) showed only traces of -2.1°C waters, indicating that the northward branch of the ISW circulation cell may be found there (Figure 1). Overall, at depths below 400 m, Filchner Trough was entirely occupied by ISW with temperatures of -2.0°C and salinities of >34.55 , except for a more saline ($34.60\text{--}34.65$) near-bottom layer (10s of meters thick) that was just below the freezing point (Figure 7). These densest bottom waters circulate in Filchner Trough and result from a mixture of HSSW formed on Berkner Bank with the ISW outflow from underneath FIS. Most of these waters are too dense to spill northward over the ~ 500 m deep sill separating Filchner Trough from the deep Weddell Sea and will thus remain confined to Filchner Trough. The overflowing waters observed north of the sill (Figure 6, transect 4) are characterized by slightly lower density of $\sim 0.05\text{ kg m}^{-3}$ (Figure 7) and thus originate from the ISW layer of -2.1°C to -2.0°C that occupy the 400–700 m depth layers (transect 3). The cold overflow in transect 4 was overlain by mWDW with maximum temperatures of almost 0°C and salinities of $34.5\text{--}34.6$. The upward-sloping isohalines indicate enhanced northward transport at the western side of the transect, while the stations east of 31°W featured mWDW all the way to the bottom. The 2018 water mass distribution in the northern trough resembled conditions similar to those observed during earlier expeditions, as for example in 2003 (e.g., Darelus et al., 2014b). The easternmost station in transect 4 showed ISW with a lower salinity of 34.3 (Figure 7), which points to a shallower source from underneath Brunt Ice Shelf.

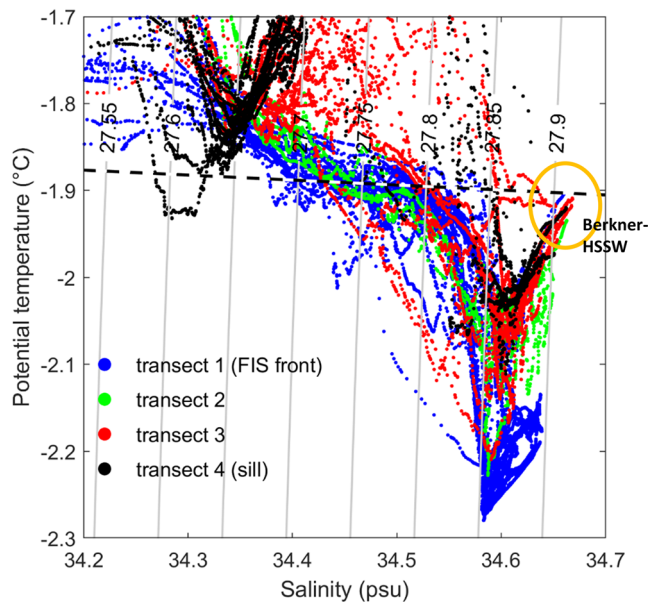

Figure 7. Temperature-salinity-diagram from CTD stations in Filchner Trough, representing water masses at and below surface freezing. Colors code the individual transects, shown in Figure 6. The yellow circle highlights the near-bottom properties related to Berkner-HSSW. σ_t -contours from 27.55 to 27.9 kg m^{-3} are marked by gray contours, the surface freezing temperature relative to salinity is shown by the black dashed line.

4. Discussion

4.1. Decadal Variability in Front of RIS

Sea ice conditions during early 2018 allowed us to survey the water masses of a ~ 750 km long stretch along the FRIS front with unprecedented spatial resolution. Only a few expeditions have been able to access both FIS and RIS, though not with the high spatial resolution sampling grid that was accomplished during PS111. Two such similar expeditions were carried out in austral summers of 1980 and 1995 and allow for a comparison across a four-decade time period. Similar temperature and salinity features to those shown in Figure 3 are evident in all three surveys, although the station coverage was not as spatially dense in the historic surveys. The minor thermohaline differences are therefore best displayed and compared using temperature-salinity-diagrams (Figure 8). Minimum temperatures of -2.25°C recorded in 2018 were as low as in 1980, and only marginally warmer in 1995 (Figure 8a). Salinities at the ISW temperature minimum were slightly (~ 0.02 psu) lower in 2018 compared with the other two periods in Filchner Trough (Figure 8c). In Ronne Depression, HSSW prominently appeared in all three surveys, with maximum salinities in 1995 and 2018 of >34.80 , and slightly lower maximum salinities in 1980 of 34.78 (Figure 8b). The minimum temperature in the ISW outflow at 58°W in 2018 was -2.1°C and thus slightly lower than the other two years. This is consistent with slightly higher GBMW fractions of 0.7% in 2018 compared with 0.5% observed in 1995 inside the ISW outflow (Figure 4). The inflow of mWDW along Central Trough existed in all surveys with minor temperature differences between these years. However, the mWDW inflow is remotely controlled by slope front dynamics (Daae et al., 2017). This is further underlined by moored temperature

records near the ice shelf front at 53°W , which showed considerable seasonal and interannual variability in the water mass properties (Foldvik et al., 2001), similar to the variability reported for the Filchner Trough mWDW inflow (Ryan et al., 2020). Therefore, observed differences between CTD snapshots can arise from the surveying point in time and should not be overemphasized.

The conditions in front of RIS remained remarkably constant over time, despite the effect of the grounded icebergs after 1987 (Grosfeld et al., 2001; Nøst and Østerhus, 1998). Flow features likely stayed in the same locations due to topographic steering of the currents. One explanation for the relatively stable hydrography there may be that sharp salinity gradients developed during strong polynya events can lead to baroclinic instabilities (Chapman & Gawarkiewicz, 1997; Jenkins et al., 2004), which mix excess HSSW salt patches either into the cavity or northward. The ISW-outflow on the eastern flank of Ronne Depression is the northward extension of the sub-ice shelf circulation observed by Nicholls et al. (2004) and a comparatively small but constant feature, with most of its core at -2.0°C . The “warm” ISW temperature indicates that the HSSW-modification took place at a shallow ice shelf base (i.e., not far inside the cavity) with only a slightly lowered freezing point relative to the surface. The GBMW fractions are only slightly elevated in both 1995 and 2018 (0.5%–0.7%) (Figure 4), and the tracer-based water mass dating indicates that the ISW is only 1–2 yr older than its Ronne-HSSW source water (Figure 9). The ISW mixes with the adjacent waters soon after exiting RIS and is no longer observed as a distinct water mass on the southwestern Weddell Sea shelf (Nicholls et al., 2004). Earlier mooring records from the RIS front show flow parallel to the ice front, which was explained by blocking due to denser HSSW and northwestward diversion of the ISW outflow parallel to the RIS edge (Foldvik et al., 2001; Nicholls et al., 2004). Ronne Depression is the deepest part of the notice shelf-covered southwestern Weddell Sea shelf (Figure 1) and thus collects all dense waters formed in front of RIS. Therefore, each late summer hydrographic CTD snapshot along RIS samples the accessible remains of a reservoir with flushing time scales of roughly 10 yr (Huhn et al., 2018). These long time scales explain the remarkably stable hydrography along RIS and hence provide only limited information regarding the processes taking place underneath FRIS. The anthropogenic tracer-based dating in front of RIS at

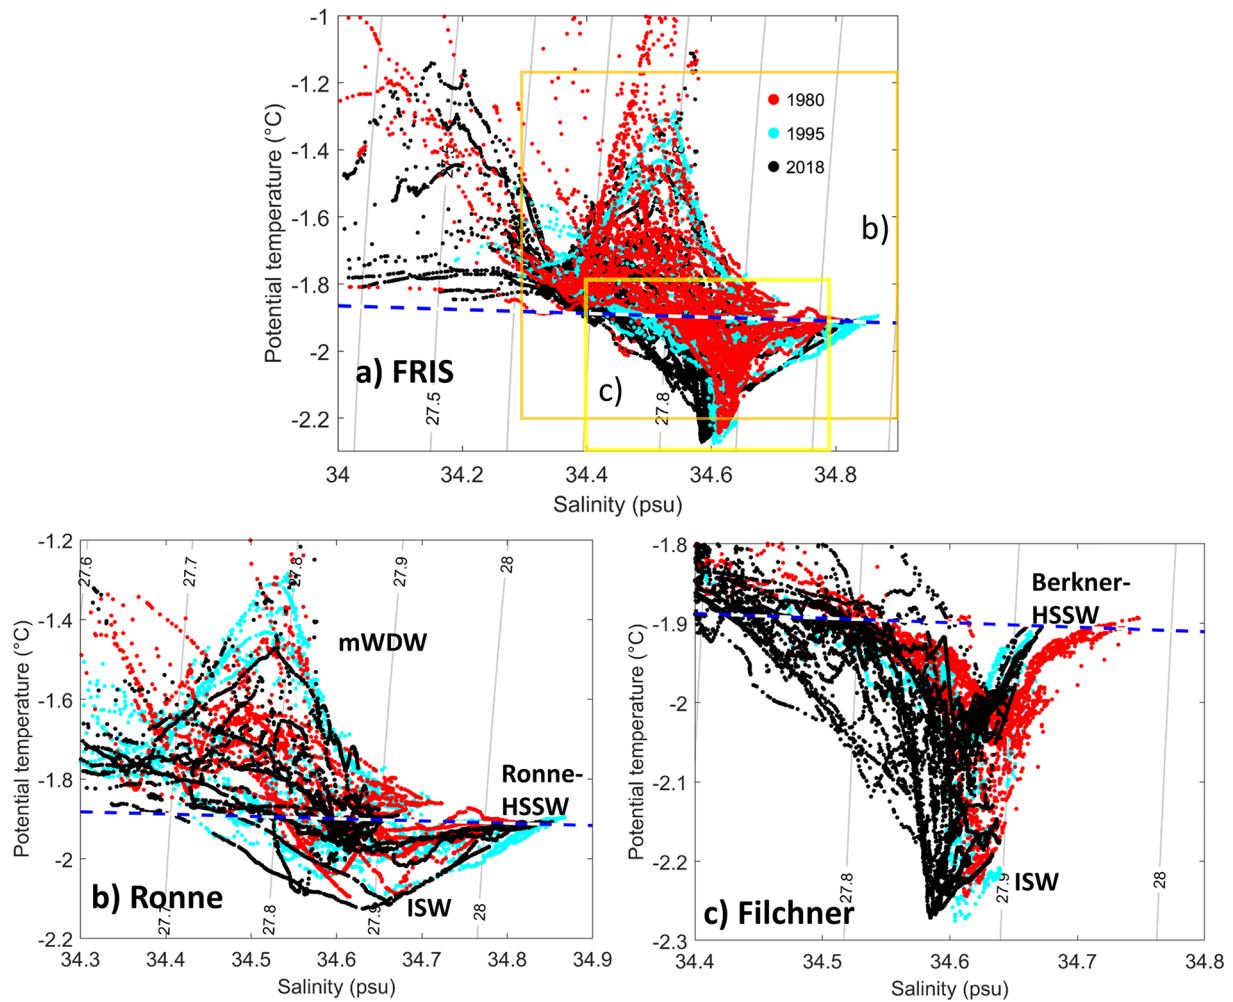

Figure 8. (a) Temperature-salinity-diagram from all CTD stations along FRIS, (b) from Ronne (west of 50°W), and (c) Filchner (east of 43°W) CTD stations from 1980 (red), 1995 (cyan), and 2018 (black). Station locations are shown in Figure 1. σ_t -contours are shown in black lines in 0.1 kg m⁻³-increments. The dashed line indicates the surface freezing temperature. Yellow boxes in panel (a) indicate the temperature-salinity-properties of panels (b) and c).

Figure 9. Water mass age based on the SF6/CFC12-ratio (see data and methods section) along the FRIS front. The bathymetry is based on station depth inferred from CTD profiles. Data are interpolated between the data points (black dots) and displayed in 1 yr color contours. ISW outflows are marked with white arrows.

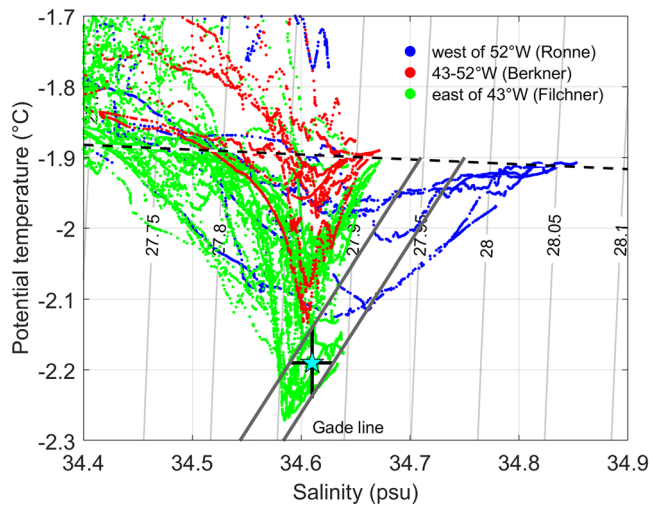

Figure 10. Temperature-salinity-diagram from CTD stations along FRIS. Colors differentiate between Ronne (blue), Berkner (red), and Filchner (green) stations. The blue star marks the mean temperature and salinity of ISW colder than -2.1°C including the standard deviations indicated by the vertical and horizontal lines. The Gade lines bound possible source water salinities (without considering mixing) at the intersection with the line of surface freezing points (black dashed line). The Gade lines neglect the effect of heat conduction into the ice and use a slope of 2.4 K/psu .

58°W – 60°W determined the HSSW water mass age to be 4–6 yr old (Figure 9), which may be partly due to older recirculating ISW on the eastern flank of Ronne Depression (Figure 3a). The old water mass age supports the concept that these winter-formed waters pool and contribute to a stable long-term reservoir without swiftly changing conditions. Apart from difficult sea ice conditions in the southwestern Weddell Sea that often inhibit ship-based access, our conclusions suggest that frequent surveys of the RIS edge region may not be needed due to the long time scales. However, since HSSW-production varies interannually and the associated volume transports into the cavity drive the circulation underneath FRIS, as will be discussed in the following, it would be desirable to obtain time series measurements of volume transports across the RIS front.

4.2. On the Hydrographic Transition Between 2017 and 2018 at the FIS Front

The most striking feature during our 2018-survey in Filchner Trough was the large ISW-covered cross-area with temperatures of $<-2.2^{\circ}\text{C}$ (Figures 3a, 6 transect 1). Well-defined ISW cores at similar temperatures were seen in earlier surveys, such as in 1973 (Carmack & Foster, 1975), 1980 (Foldvik et al., 1985), or 2017 (Darelius & Sallée, 2018). However, these ISW cores were limited to the western flank, while in 2018 the ISW below -2.2°C was found across the entire width of Filchner Trough. The source of the ISW observed in the trough can be inferred by applying Gade lines (Gade, 1979) in a temperature-salinity diagram. Following

Hutchinson et al. (2020), we applied the Gade lines based on the mean temperature and salinity of the waters below -2.1°C and their standard deviations (Figure 10). The Gade line with a slope of 2.4 K/psu traces the observed ISW temperatures to the surface freezing temperature and identifies a range of resulting source salinities of 34.7 – 34.75 . This is lower than the observed maximum Ronne-HSSW salinities of 34.84 but more saline than any other water mass sampled along FRIS. Considering that HSSW flowing underneath RIS enters a tidally energetic environment (Makinson, 2002; Makinson & Nicholls, 1999) and mixes with local water masses of likely lower salinities, we conclude that the observed ISW in Filchner Trough could only have been sourced by Ronne-HSSW.

The 2018-conditions contrast with those observed one year earlier in 2017, when a CTD and stable isotope tracer survey found that Berkner HSSW-sourced ISW dominated in Filchner Trough (Akhoudas et al., 2020). These two different hydrographic conditions are referred to as Berkner- and Ronne-modes, and are mainly manifested by contrasting hydrographic conditions underneath the northern FIS and in Filchner Trough, as schematically illustrated in Figure 11. The two modes can also be understood as a measure of sub-FRIS circulation, forced by the production of Ronne-HSSW. When Ronne HSSW-production is weak, the local Berkner-HSSW dominates in the Filchner region, as observed in 2017 (Akhoudas et al., 2020), and is also able to enter the northern parts of FIS (Figure 11a). In contrast, an enhanced FRIS-circulation fueled by stronger inflow of Ronne-HSSW leads to enhanced ISW outflow from underneath FIS, which results in the dominance of Ronne-sourced ISW along the FIS front and in Filchner Trough, as observed in 2018 (Figure 11b).

Besides the Filchner Trough snapshot observations made in 2017 (Akhoudas et al., 2020) and 2018, a transition from Berkner-to Ronne-sourced waters was observed by drill hole moorings, which recorded CTD time series throughout this period at different locations underneath FIS (H2021, see Figure 1 in this paper for drill hole mooring locations). As illustrated in Figure 11 and shown by Figure 2 in H2021, the mooring locations deep inside the cavity only feature Ronne HSSW-sourced water masses. The northern FIS drill hole moorings, however, can be affected by circulation changes in Filchner Trough and thus were able to show the gradual transition from Berkner-sourced ISW in early 2017 to the Ronne-sourced waters in early 2018 (H2021) that we observed in Filchner Trough during PS111.

Figure 11. Schematic representation of the regional circulation and its impact on the northern FIS edge during (a) Berkner- and (b) Ronne-modes. The top panels indicate a map view of the circulation, while the bottom panels represent a meridional cross-section of the FIS edge. The Berkner-mode is dominated by Berkner-HSSW in Filchner Trough, associated with enhanced melt rates at the northern base of FIS. The Ronne-mode features an enhanced circulation in the cavity with an enhanced outflow of ISW from underneath FIS. Basal melting is reduced at northern FIS, but is enhanced inside the cavity. Circulation arrows are based on insights gained from the 2018 CTD survey and drill hole moorings (H2021) as well as from earlier literature-based findings.

The transition to a greater dominance of sub-FRIS waters in Filchner Trough is also reflected in GBMW fractions. Based on measurements from the same drill holes as discussed above (Figure 1), Huhn et al. (2018) report neon-based GBMW baseline fractions of 1.0%–3.6% directly at the FIS base, and lower fractions of <0.4% near the bottom of the northern FIS and in Filchner Trough in 2016. These values are consistent with the (stable oxygen isotopes-based) fractions of 0.4% in Filchner Trough in 2017 reported by Akhoudas et al. (2020). In 2018, the FIS front was dominated by ISW, coincident with the highest water mass age (Figure 9) and elevated GBMW fractions of 0.8%–1.0% below a depth of 600 m. These fractions directly agree with the fractions measured by Huhn et al. (2018, see their Figure 3) at the northern FIS drill hole sites. Our observations overall indicate an intensified sub-ice shelf circulation, which led to a flushing of older water masses from the FRIS cavity into Filchner Trough, characterized by higher melt water fractions and low temperatures. This flushing was likely forced by a recent intensification of sea ice formation and HSSW-production north of RIS (Figure 12), as will be discussed in the following section.

The impact of varying circulation modes is most notable beneath the northern FIS and in Filchner Trough. Stronger inflow of HSSW via Ronne Depression leads to enhanced input of heat into the ice shelf cavity, which will be available for ice shelf melting and ISW production underneath RIS. Furthermore, stronger inflow results in intensified outflow of ISW at the FIS front, which limits melting at the northern FIS edge. Instead, freezing underneath the ice shelf increases due to a combination of ascending ISW and a rise of

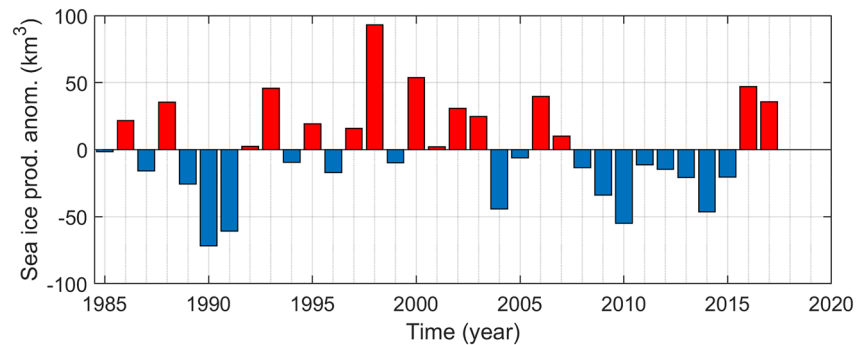

Figure 12. Sea ice production anomalies in the Ronne sector (white area in Figure 1) from 1985 to 2017 based on a simulation with the Finite Element Sea ice Ocean Model (FESOM; Timmermann et al., 2012) forced with data from the ERA-Interim reanalysis. The anomalies are shown relative to the mean sea ice production of $116 \text{ km}^3 \text{ yr}^{-1}$.

the local freezing temperature (Figure 11b). In contrast, in the absence of a significant northward flow out of FIS, Berkner-HSSW circulation is strong enough to impact the FIS front and locally enhance ice shelf melting (Figure 11a). This concept is supported by time series from two ApRES (autonomous phase-sensitive Radio Echo Sounders), deployed at and near a drill hole on the northeastern FIS. Basal melt rates there decreased from 1.3 m per year in 2017 to 0.8 m per year in 2018 (H2021).

4.3. Decadal Variability of Ronne- and Berkner-Sourced ISW in Filchner Trough

In contrast to the low interannual variability of the hydrographic structure along RIS, the conditions off FIS are subject to greater variability impacted by local HSSW-production as well as the strength of the sub-FRIS circulation and outflow. Historical data derived from expeditions over more than four decades on the southern Weddell Sea continental shelf underline the variability and shift between Ronne- and Berkner HSSW-sourced ISW in Filchner Trough, as represented by near-bottom salinity in front of FIS (Figure 13). First, the ~ 0.5 psu higher initial sea surface salinities in the southwest (Figure 2b) explain the more saline Ronne-HSSW compared with Berkner-HSSW. Further, the bathymetry underneath FRIS guides Ronne-HSSW far into the cavity and toward greater pressure, which increases the basal melt potential, resulting in colder and fresher ISW. Berkner-HSSW, however, enters the shallower cavity west of Berkner Island or flows directly into Filchner Trough, and therefore interacts with the ice base at significantly shallower depths (Figure 11). This results in warmer and more saline ISW compared with Ronne HSSW-sourced ISW (see H2021). The two modes are therefore categorized by near-bottom salinities as measured in front of FIS of <34.65 (Ronne-mode, source salinity >34.7) or >34.65 (Berkner-mode, source salinity <34.7) (Figure 13). The near-bottom salinities in Filchner Trough from surveys across a 45 yr time period indicate a considerable spatial and interannual variability in near-bottom water properties, suggesting that water mass characteristics alternated regularly between Ronne HSSW-derived ISW and Berkner-HSSW. However, despite relatively clear differences in the source salinities characterizing Ronne- and Berkner-modes, the densities vary only little and not consistently (not shown). For the stations considered in the source salinity computations (encircled in Figure 13), the mean potential density at depths below 600 m is $27.88 \pm 0.13 \text{ kg m}^{-3}$, and varies less than 0.05 kg m^{-3} between the different surveys. This small range of FIS front densities, independent of the prevailing circulation mode, is still above the potential density of mWDW ($\sim 27.8 \text{ kg m}^{-3}$, Figure 8), which suggests that alternating modes do not directly impact the mWDW inflow dynamics. However, the bias in the available station distribution in the southern Filchner Trough limits the statistical significance of this analysis.

A strong Ronne-dominance as observed in 2018 leads to outflowing ISW on the western Filchner Trough slope, flushing the shelf in the Berkner-HSSW formation regions (Figures 3a and 11b). The formation of HSSW on Berkner Bank requires that surface waters reach the density of the Ronne HSSW-sourced ISW to convectively mix the water column. Once denser, the Berkner-HSSW will be able to spread and restrict the northward flow of Ronne-sourced ISW underneath FIS. Radar-sensed basal melting near the FIS front is indeed enhanced when induced by Berkner-HSSW (H2021), which produces ISW outflows that are less

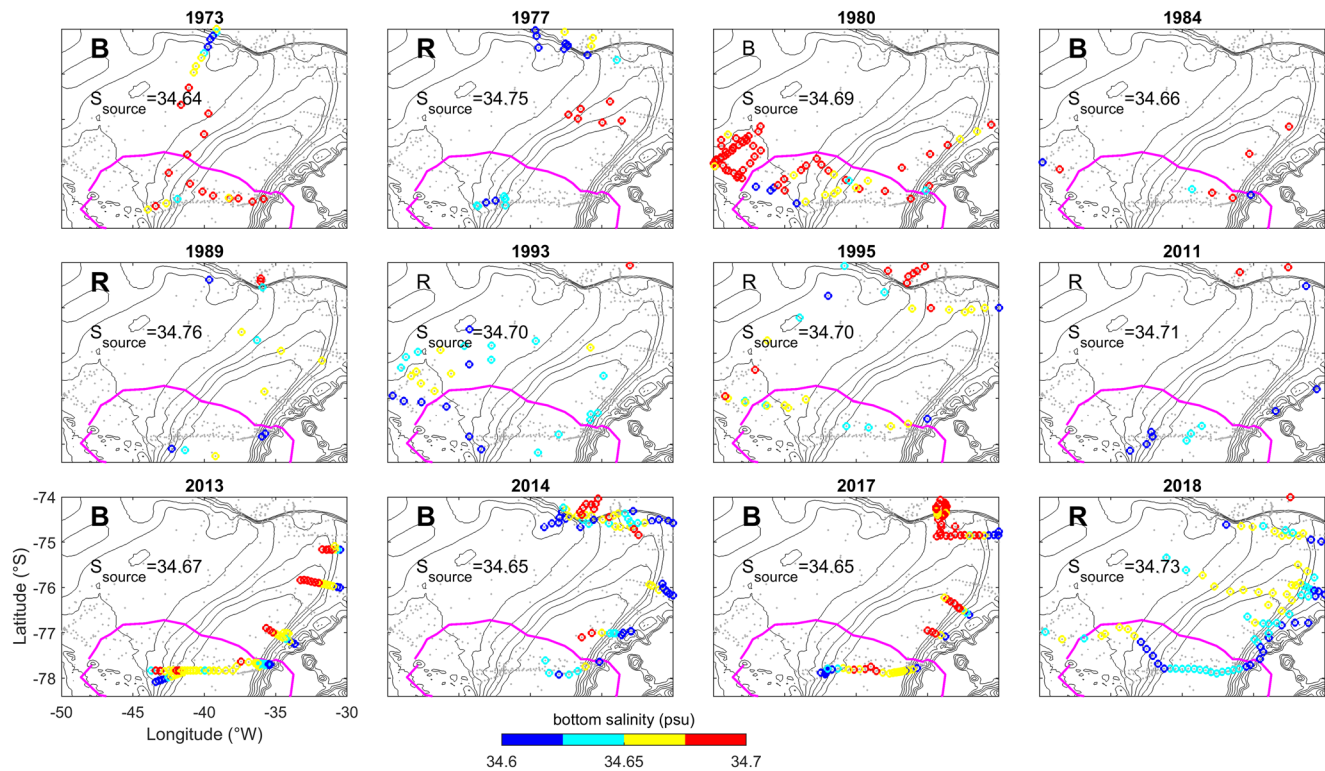

Figure 13. Maps of the Filchner region showing near-bottom salinity observed from CTD surveys since 1973. The magenta line encircles those profiles used for averaging the source water salinity of the ISW in front of Filchner Ice Shelf in order to identify the dominant circulation mode. Source salinities >34.70 and <34.70 indicate Ronne and Berkner-modes, respectively. Berkner (“B”) or Ronne (“R”) mode conditions are marked by the respective letter in the upper left, the mean source salinity is provided below in each panel. A bold letter indicates that the mode is statistically significant within one standard deviation. A non-bold letter indicates statistical insignificance, i.e., too few data points or mean source salinities close to 34.70. Bathymetry (Schaffer et al., 2016) is displayed by black contours in 100 m isobaths.

dense than the Ronne HSSW-sourced ISW. Hence, without enhanced sea ice formation in the Ronne polynya driving a more vigorous cavity circulation, fresher FIS outflows would set up a feedback loop that continuously reduces the density of the Berkner-HSSW. This would promote a transition to fresher water masses in Filchner Trough with consequences for the processes at the continental shelf break. The fact that ocean densities in the lower Filchner Trough remained remarkably stable under shifting source water types in the past suggests that an oscillating dominance of the two circulation modes may indeed be part of the internal variability that interacts with the varying forcing of the system.

Sea ice production and the resulting salt fluxes in the southwestern Weddell Sea are the main source for Ronne-HSSW, which is the driver of the circulation underneath FRIS. Sea ice production primarily depends on air-sea heat fluxes, which are further controlled by winds, sea ice concentration, and water column structure. In particular, extended periods of southerly and southwesterly winds lead to polynya events and, consequently, large sea ice formation rates. This connection between large-scale atmospheric conditions and sea ice formation in the southwestern Weddell Sea is further discussed by H2021, who found that a westward displacement of the Amundsen Sea Low leads to enhanced southerly winds over RIS associated with positive phases of the Southern Annular Mode (SAM). For instance, a positive SAM along with vast open water areas in 1998 coincided with the highest sea ice production rates within the last three decades (Figure 12; Haid & Timmermann, 2013; Nicholls & Østerhus, 2004). Sea ice production in the southwest Weddell Sea showed a decreasing trend after 2006 (Figure 12) coincident with a decreasing number of polynya days (Paul et al., 2015), which likely resulted in the lower presence of Ronne HSSW-sourced ISW in Filchner Trough before 2017. Nevertheless, sea ice production increased again thereafter with two positive anomalies in 2016 and 2017 in response to a period of synoptically enhanced southerly winds (H2021), which then set up the conditions observed in 2018.

5. Summary and Conclusions

This paper provides a 2018-status update on the hydrographic conditions along the entire length of FRIS in the southern Weddell Sea, based on a tightly spaced CTD and noble gas tracer survey. The conditions found off RIS were similar to those previously described, including a strong presence of HSSW in Ronne Depression, a core of outflowing ISW and an inflow of mWDW from Central Trough (Nicholls et al., 2003). Filchner Trough, however, was strongly dominated by ISW (temperature $< -2.0^{\circ}\text{C}$) along the entire ice shelf front, with a well-defined core of $< -2.2^{\circ}\text{C}$ -Ronne HSSW-sourced ISW, and only slightly warmer (-2.1°C) water below ~ 700 m (Figure 6). The outflowing ISW core leans against the western flank of Filchner Trough and is identifiable in both geostrophic velocities (Figure 5) and noble gas tracers (Figures 3d–3e, 4, and 9). Anthropogenic trace gases were used to date water masses, and the difference in water mass age between the source waters off both FIS and RIS provides insights into the circulation time scales (Figure 9). These analyses indicate a two-year travel time from Ronne Depression to the western slope of Filchner Trough at the FIS front, which agrees with earlier estimates of the direct route around Berkner Island (Nicholls & Østerhus, 2004). A less direct route through the deeper cavity must have been taken by those waters exiting via the central and eastern Filchner Trough, indicated by water masses more than 6 yr older than the Ronne-HSSW source waters (Figure 9). Additional northern CTD transects (Figure 6 transects 2 and 3) show waters colder than -1.9°C in the entire Filchner Trough to the north, as well as north of the sill below 400 m (Figure 6 transect 4). These observations exemplify the export of dense FRIS-formed ISW across the sill to the Weddell Sea continental slope, widely known as a precursor for AABW and thus important for the global overturning circulation. Based on noble gas tracers, we found a maximum GBMW content of 1.0% in the coldest ISW-core and 0.6%–0.9% in the remaining ISW along the FIS front. This was close to the fractions found a few years earlier underneath FIS (Huhn et al., 2018) and not significantly different from those regions that were also measured in 1995 (Figure 4). While Filchner Trough featured Berkner-derived water mass characteristics in 2017 (Akhoudas et al., 2020; Darelus & Sallée, 2018), our 2018-survey was dominated by Ronne-sourced properties, underlining the recent shift from Berkner-to Ronne-mode (Figure 11) first identified by moorings underneath FIS in mid-2017 (H2021). This shift follows two years of strong sea ice formation in the southwestern Weddell Sea (Figure 12) and thus enhanced production of Ronne-HSSW, which fuels the circulation underneath FRIS and impacts the ice shelf-ocean interaction in two ways. First, the shift changes the spatial distribution of basal melting with lower rates near the FIS front and higher rates at greater depth inside the cavity (Figure 11). Second, dense ISW production is promoted, which is important in maintaining dense shelf waters that effectively block any larger-scale influence of mWDW. This water mass of open ocean origin is generally present at the Filchner Sill and known to penetrate southward along the eastern slope of Filchner Trough (Ryan et al., 2017).

The importance of HSSW and ISW as precursors for AABW broadens the importance of the sea ice production and processes taking place underneath FRIS, as $\sim 50\%$ of the deep water formed in the Southern Hemisphere originates from the Weddell Sea (Meredith, 2013). The southern Weddell Sea receives fresher Eastern Shelf Water via the coastal current (Nicholls et al., 2009), which contributes to the observed increasing sea surface salinity from 33.5 to 34.5 toward the southwest (Figure 2b) and the overall higher salinity and density of the Ronne-HSSW compared with HSSW formed on Berkner Bank. A strong Ronne-dominance as observed in 2018 leads to ISW outflow on the western Filchner Trough slope and also preconditions the ocean conditions in the Berkner-HSSW formation region (Figure 3). This recycling of ISW on the continental shelf suggests an internal feedback loop that would lead to a continuous freshening in Filchner Trough in the absence of dense water supply from Ronne Depression under a sustained Berkner-mode. Instead, the relatively stable density seen in historical data from Filchner Trough suggests that the regular alternations between Ronne HSSW-derived ISW and Berkner-HSSW may be part of the internal variability of the system. However, the sparse station coverage between the different surveys (Figure 13) limits our understanding of the relevant processes, formation mechanisms, and climatic importance of the Ronne-vs.-Berkner-mode discussion.

Overall, the FRIS system is strongly controlled by sea ice production in the southern Weddell Sea, which depends on polynyas caused by off-shore winds advecting cold air from the Antarctic continent. The recent return to a Ronne-mode has been linked to anomalies in the synoptic circulation over and east of the Antarctic Peninsula (H2021). If these anomalies would continue to persist under climate change, a

strengthening of the density barrier at the continental slope, maintaining low melt rates of FRIS, could be a possible response. However, HSSW-formation depends on surface forcing and on sea surface properties impacting stratification. For instance, local changes in sea ice formation or glacial melt distribution, as might be expected under continued warming (Hellmer et al., 2017; Timmermann & Hellmer, 2013), may negatively impact the dense water production on the southern Weddell Sea continental shelf and thus weaken the oceanic protection of FRIS. The global importance of the Antarctic Ice Sheet underlines the need for in situ observations such as those collected during 2018 as well as from moorings on the shelf and underneath FRIS, complemented with autonomous platforms such as floats and gliders. Such detailed observations are necessary to monitor potential changes around FRIS and to advance the process understanding in order to improve numerical models and reduce their uncertainties in projecting future sea level rise.

Data Availability Statement

Andreas Wisotzki carefully measured oxygen content from water samples during the expedition and processed the PS111 CTD data, downloadable under: <https://doi.org/10.1594/PANGAEA.897280>. Additional datasets used in this paper can be found at: <https://doi.org/10.1594/PANGAEA.860066> and <https://folk.uib.no/ngfso/Data/CTD/> (historic 1995 and 1980 CTD data), <https://doi.pangaea.de/10.1594/PANGAEA.895579> (PS111 thermosalinograph); <https://doi.pangaea.de/10.1594/PANGAEA.913625> (PS111 meteorology); <https://doi.pangaea.de/10.1594/PANGAEA.930718> (tracer data).

Acknowledgments

This study used samples and data provided by the Alfred Wegener Institute Helmholtz-Center for Polar- and Marine Research in Bremerhaven (Grant No. AWI-PS111_01). The authors thank Captain Schwarze and the crew of RV Polarstern for a very successful expedition. We acknowledge support from the EU Horizon 2020 grants 820575 (HHH, SØ) and 821001 (TK, SØ). We thank Elin Darelus for helpful comments. The authors greatly appreciate the thorough reviews and constructive criticism of Katherine Hutchinson and one anonymous reviewer and thank the editor Laurie Padman for his efforts in handling our paper.
