## ABSTRACT

During September 1985, four hauls were made with a 1 m<sup>2</sup> MOCNESS equipped with 333 µm mesh nets to collect zooplankton from depths between 3400 and 4700 m in the eastern North Atlantic. These depths ranged from 220 to 1500 m above the sea floor. Data lists for 30 of the samples are presented. The preliminary results and performance of the device are discussed.

The biomass and total numerical abundance fell well within the relatively wide ranges reported in the very limited body of literature. Calanoid copepods constituted the most important taxonomic group with relative numerical abundances of 41 to 82.5 %. Chaetognaths and ostracods followed in order of abundance. Vertical gradients in abundance were apparent for smaller taxonomic groups within the Copepoda. In the discussion, special attention is paid to differences in the structure of the plankton community relative to the distance from the bottom.

## 1. INTRODUCTION

The multidisciplinary German research program, BIOTRANS (Biologischer Vertikaltransport und Energiehaushalt in der bodennahen Wasserschicht der Tiefsee), focuses on ecological processes at the bottom and in the overlying 500 m of the water column in the deep bathyal and upper abyssal zones (THIEL 1986). One important aspect of our zooplankton investigations is the vertical gradients of both abundance and taxonomic composition relative to the distance from the bottom. Several authors reported increases in zooplankton or micronekton abundance with depth within 100 m of the deep-sea floor (WISHNER 1980a; ANGEL & BAKER 1982; SMITH 1982; ELLIS 1983; HARGREAVES 1984, 1985; HARGREAVES et al. 1984; DOMANSKI 1986; ROE 1986; ROE et al. 1986; SMITH et al. 1986). Gradients in abundance are obviously accompanied by distinct changes in the taxonomic structure of the pelagic community (for zooplankton see WISHNER 1980b; ROE 1986).

The survey described herein encompassed the zone from about 200 to 1500 m above the bottom and yielded the first detailed information on the zooplankton community structure within the upper parts of the bottom nepheloid layer. In the area chosen for the BIOTRANS project, the thickness of this layer was found to be as much as 1000 m (NYFFEGER & GODET 1986).

Quantitative data from below 2000 m on the total amount of zooplankton and its taxonomic composition are extremely rare in the literature. Most relevant research was restricted to major taxonomic groups, such as calanoid copepods (e.g. GRICE & HÜLSEMANN 1965, 1967; WHEELER 1970) or ostracods (ANGEL 1983). Exceptions are the first ecological near-bottom study of WISHNER (1980b), the comprehensive work of VINOGRADOV (1968), and a small amount of data provided by COLMAN (1962), GREZE (1963), and SCOTTO DI CARLO et al. (1984). Therefore, complete data lists for the sample series from the deep bathyal and abyssal zones are regarded as useful and presented in the Appendix.

## 2. MATERIAL AND METHODS

### 2.1. Sampling and sorting procedures

During the first leg (BIOTRANS III) of cruise 08 (ANTARKTIS IV) of the RV "POLARSTERN", 30 zooplankton samples were obtained from four hauls with a MOCNESS (Multiple Opening/Closing Net Environmental Ssensing System; WIEBE et al. 1976, 1985) in the Northeast Atlantic at depths between 3400 and 4700m (BECKMANN 1986). At the optimal angle of 45°

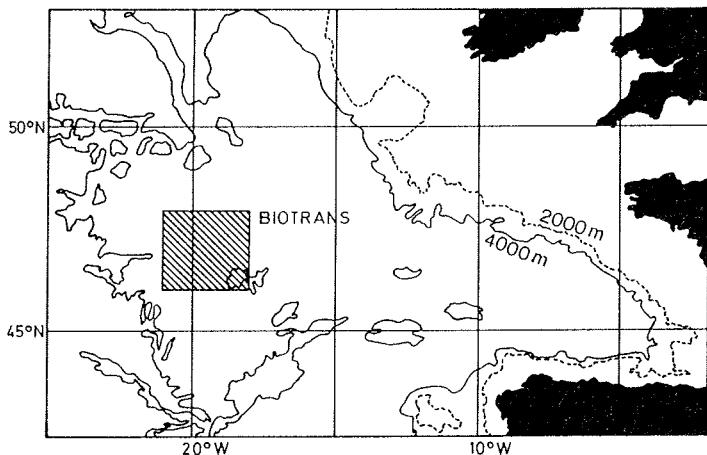

between its frame and the direction of water flow, the system filters an area of 1 m<sup>2</sup>. The angle of the frame to the vertical axis is measured with an inclinometer attached to the apparatus, and this value plus the angle of deviation of the towing direction from the horizontal axis remained between 32° and 58° during the hauls. Hence, an optimal filtration efficiency of the nets is assumed.

The 1m<sup>2</sup> MOCNESS was equipped with nine 333μm nets, which were sequentially operated via a conductor cable. In order to stabilize the device, it was lowered to the maximum depth with the first net open. Samples from this net, which moved through nearly the entire water column, have not been considered in the study. The ship's speed during the tows was 1.5 to 2.5 knots.

Unfortunately, the sampling strategy was greatly influenced by some technical constraints. There was no opportunity to directly measure actual distances from the bottom. Moreover, repeated sampling within distinct depth ranges was often hampered by problems with the winch. During hauling, the winch had to be stopped often, and sometimes the towing cable had to be paid out again in order to wind it up correctly. In most cases, samples were taken during similar time intervals.

Figure 1 shows the sites of the MOCNESS tows, and Table 1 summarizes relevant data for each station. Samples were preserved in a 4% formalin-seawater solution buffered with hexamethylenetetramine. Biomass wet weights were determined using the method of TRANTER (1962). Large organisms ( $\geq 1.5$  cm) were removed before weighing. Samples from nets 2 and 9, i.e., the first and last ones taken during each haul, were excluded from biomass determinations because of a significantly increased rate of contamination during passage through the shallower layers.

A main problem in sorting deep-sea zooplankton is the reliable separation of animals that had been alive at time of collection from molts and carcasses. This is difficult because the organisms remain in the nets for a long time, up to eight hours during this study, before they can be preserved. In order to distinguish living from dead copepods, the criteria of WHEELER (1967) were applied: the condition of the swimming legs and the presence of tissue in the first antennae. WISHNER (1980b) counted all specimens containing any traces of organs or tissues as living, taking into account tow durations of up to 17 hours. Among the specimens caught during the BIOTRANS investigation, several individuals with tissue remains in their bodies had to be regarded as dead prior to collection. However, to a certain extent, the categories "alive" and "dead" remain subjective.

In the Appendix, the counts of living deep-sea specimens, contaminants, and dead animals are compiled separately for each of the 30 samples according to the taxa. Since a detailed taxonomic evaluation of the material is still in an initial phase, additional remarks on most of the groups precede the lists.

## 2.2. Calculation of water volumes filtered

Generally, the MOCNESS is equipped with a flow meter. This and the continuous measurement of the angle of the net frame to the vertical axis with an inclinometer enable a fairly good estimation of the water volume filtered by each net, if the deviation of the towing direction from the horizontal axis is included in the calculations (WIEBE *et al.* 1985). Flow meter data were not available during this study. Therefore, the volume was estimated using several other parameters, such as ship's speed, wire length at opening and at closing the nets, depth change of the system, and angle of the frame to the vertical axis. While lowering or raising the MOCNESS, the changes in the area filtered relative to that calculated for the angles detected by the inclinometer were considered. In four cases (Haul 6, nets 6 through 9), some of the data needed for the volume calculation were somewhat inaccurate, and the reported volumes may deviate up to 20% .

### 2.3. Calculation of distances from the bottom

Depth ranges from the bottom for each net were determined by estimating the position of the MOCNESS relative to the ship's position and correlating the local water depths with the system's pressure meter records. The local water depths were determined with a Honeywell Elac echosounder and from detailed SEA BEAM maps (HEINRICH 1986). All hauls were conducted above flat plains with gradual topographic changes that generally did not result in depth differences greater than about 100 meters during a complete haul (Fig. 1). The distances calculated above the bottom were rounded off to the nearest five meters and should be accurate in the range of  $\pm 20$  m. The main source of error is an overestimation of the distance of the MOCNESS from the ship, due to the assumption of a straight towing cable for the calculations.

## 3. RESULTS AND DISCUSSION

### 3.1. General problems encountered in quantitative sampling of deep-sea zooplankton

Many quantitative zooplankton data from depths below 2000 m have been obtained from vertical net hauls at sampling intervals of 1000 m or more (COLMAN 1962, GREZE 1963, GRICE & HÜLSEMANN 1965, 1967, VINOGRADOV 1968, KING *et al.* 1978, IANORA & SCOTTO DI CARLO 1981, SCOTTO DI CARLO *et al.* 1984). Sampling narrower depth strata increases the risk that the small water samples would be especially prone to small-scale variability (WISHNER 1980a). Moreover, unfavourable ratios of deep-sea organisms to contaminants from shallower layers are found because of the low deep-sea plankton abundance. SMITH (1985) and SMITH *et al.* (1986) caught deep bathyal and abyssal near-bottom zooplankton using the "slurp gun respirometer" operated from a submersible vehicle. Their goal was to collect zooplankton in good physiological condition, and the small water volumes sampled "may be insufficient to provide a good estimate of abundance due to spatial variations in macrozooplankton distribution" (SMITH 1985). WISHNER (1980a,b) used a small net with a  $0.16 \text{ m}^2$  area at its opening attached to a deep tow system. However, animals collected during extremely long tows are badly damaged or have even decomposed before preservation.

Consequently, horizontally or obliquely towed multiple net systems with larger filtration areas are most suitable for profiles with a fine depth resolution. Thus, British researchers employed the RMT 1+8M (ROE & SHALE 1979) for sampling zooplankton and microneuston at bathyal and abyssal

depths (ANGEL & BAKER 1982; ANGEL 1983; HARGREAVES 1984, 1985; HARGREAVES *et al.* 1984; ELLIS 1985; DOMANSKI 1986; ROE 1986; ROE *et al.* 1986).

### 3.2. Sampling performance of the MOCNESS

The sampling performance of the MOCNESS will be briefly discussed because this apparatus has not been employed previously at such great depths.

For all four MOCNESS hauls, the data lists in the Appendix reveal a significantly greater number of organisms originating from shallower waters in nets 2 and 9 than in nets 3 through 8. Net 9 contained considerably more contaminants than net 2. The explanation is that while the MOCNESS is lowered and retrieved, the closing bar of net 9 is the most mobile because it is the uppermost one. Strong water pressure, such as that caused by wave action at the surface, may sometimes force it open, allowing organisms to enter the net. This means of contamination has already been postulated by SAMEOTO *et al.* (1980). A similar but less pronounced contamination would occur if net 2 were forced open while the device was being lowered. Its opening bar was the lowest one attached to the top beam of the MOCNESS by the toggle release.

In nets 3 through 8 only about 20 contaminant calanoid copepods were found. Considering the standing stock of over 30,000 calanoids per m<sup>2</sup> in the upper 1000 m of the water column near the sampling area during May 1985 (BECKMANN *et al.* 1987), the contamination rate of the MOCNESS must be regarded as very low (WIEBE *et al.* 1976).

### 3.3. Zooplankton abundance

Zooplankton biomass and numerical abundance were in the same order of magnitude as those reported in the sparse literature on depths greater than 2000 m (Table 2). The wet weights of two samples were very high, exceeding 1 g per 1000 m<sup>3</sup> (Table 2; Fig. 2). This was due, at least in part, to large numbers of empty euthecosomatous pteropod shells, mainly those of Limacina retroversa FLEMING (see Appendix).

Net 4 always contained the least amount of living plankton. The loss of smaller organisms, such as calanoid copepods, due to slight net damage, may have occurred in nets 4 and 7 during haul 8 (Table 1). In these two samples, the relative abundances of calanoids were lower than in the other nets, but larger polychaete and chaetognath species were relatively more abundant. The data from nets 4 and 7 during haul 8 have therefore been omitted from Figures 2 through 9.

Table 2: Zooplankton data from the deep sea (net hauls from below 2000 m depth; all data per 1000 m<sup>3</sup>). DAB: Depth above bottom (m); B: Zooplankton biomass (g wet weight); Z: Total living zooplankton numbers; COP: Numbers of living copepods; CAL: Numbers of living calanoid copepods; COPEX: Numbers of copepod carcasses excluding contaminant taxa (see text)

The abundances of living animals tended to exceed those reported by WISHNER (1980b), despite the smaller mesh-size she used and the shallower depths she sampled. The numbers of carcasses and exoskeletons were similar to those she reported (Table 2). Several explanations could be proposed:

- A high temporal and geographical plankton variability, as indicated by the few data available from the deep sea (Table 2). A seasonal effect seems unlikely as WISHNER (1980a,b) also collected her Northeast Atlantic samples during summer (July and August).
- Overestimation of the plankton abundance in this study by 1) underestimation of water volumes filtered; 2) inclusion of contaminants among chaetognaths and ostracods (see remarks in the Appendix); 3) counting carcasses as living copepods.
- Underestimation of living zooplankton by WISHNER (1980b), in spite of her exact volume calculations, due to 1) the seven-fold smaller mouth opening of her nets, which enabled some zooplankters to escape; 2) failure to count copepods that were alive at time of capture but were killed and completely decomposed during the tows of up to 17 hours, double the time of the hauls reported here. Dead:living ratios reported by WISHNER tended to increase with increasing tow duration. Her ratios for depths greater than 2000 m exceed those found in 26 of the 30 samples from my investigation, which were more similar to those calculated from the data of WHEELER (1970; Table 2). Only the ratios for haul 5, net 9; haul 6, net 4; and haul 7, nets 4 and 9 approximately conformed to WISHNER's (1980b) findings. According to WISHNER (1980b), the almost neutral buoyancy of exoskeletons may prevent them from accumulating near the deep-sea bottom. Furthermore, exoskeletons of surface-dwelling copepods are not usually found in the deep sea, possibly because they decompose rapidly in the warmer upper layers. Therefore, ratios of exoskeletons to living animals close to the sea bed are not expected to be higher than those found in overlying strata, except when near-bottom discontinuity layers (McCAVE 1986) are present. Exoskeletons of surface-dwelling copepods in my samples may be those of specimens that entered the nets as the MOCNESS was lowered and died and decomposed during the haul. When the number of these exoskeletons was subtracted from the total number (Table 2), only 2 ratios of dead to living copepods, those for haul 6, net 4, and haul 7, net 9, exceed two of the four found by WISHNER (1980b) below 2000 m.

### 3.4 Taxonomic composition and vertical distribution patterns

Gymnopleid copepods (Calanoida) were the main group within the zooplankton community, accounting for 41 to 82.5 % of the total counts of living specimens. They were followed in abundance by chaetognaths, ostracods, and podopleid copepods in decreasing order (Table 3). This order is expected to remain unchanged even if contaminants among the chaetognaths and ostracods are excluded. Similarly, COLMAN (1962) found chaetognaths and ostracods to follow copepods in rank of abundance between 2000 and 4000 m in the Bay of Biscay.

Table 3: Relative numerical abundances of major taxa in the different hauls  
(living specimens; Radiolaria excluded)

Bathypontiidae:									
<i>Foxtonia barbatula</i>	4.0	0 - 6.0	4.9	0.6- 8.4	2.4	1.1- 6.3	7.6	4.6-10.6	5.0
not identified	31.8	12.6-36.2	41.7	15.7-58.5	17.8	10.1-25.0	51.6	27.7-71.6	38.8

No distinct trends were detected in the vertical distributions of zooplankton biomass (Fig. 2), total individual numbers (Fig. 3), or the abundance of any major taxa. Such trends, however, were apparent for smaller taxonomic groups within the Copepoda.

#### Calanoida

- - - - -

On the family level, members of the Metridiidae were predominant in most samples, accounting for 13 to 68.5 % in relative abundance among all living calanoids. Apart from this family and the fraction of unidentified specimens, only Lucicutiidae exceeded 10 % in relative abundance (Table 4). Both Metridiidae and Lucicutiidae (Figs. 4, 5) increased in relative abundance toward the bottom. A corresponding increase in absolute numbers of lucicutiids is likely to occur, but this cannot be said for metridiids due to a combination of plankton variability and certain inaccuracies in the calculation of water volumes filtered, particularly for haul 6, nets 6 to 9, which sampled the upper layers (Table 1, see above).

In the water column of the North Pacific Ocean, ARASHKEVICH (1966, cited in VINOGRADOV 1968) found metridiids and lucicutiids to decrease in abundance between 500 and 8500 m. The abundance of metridiids between 2000 and 6000 m (2000-4000 m: 180 specimens per 1000 m<sup>3</sup>; 4000-6000 m: 70 specimens per 1000 m<sup>3</sup>) was similar in order of magnitude to, or possibly slightly higher than the data presented here.

Like the Heterorhabdidae (Fig. 6), the bathypontiid Foxtonia barbatula HÜLSEMANN & GRICE decreased in abundance with depth (Fig. 7). F. barbatula has to be looked upon as one of the more common deep bathypelagic organisms (Table 4). In the Northeast Atlantic, HÜLSEMANN & GRICE (1963) and GRICE & HÜLSEMANN (1965) caught the species between 2000 and 4750 m, and from the western Indian Ocean, it has been found at depths between 1900 and 3000 m (GRICE & HÜLSEMANN 1967).

#### Siphonostomatoida and Misophrioida

- - - - -

Two other copepod genera exhibited conspicuous vertical changes in abundance. Specimens of the siphonostomatoid genus Hyalopontius SARS clearly became less abundant with depth (Fig. 8). Members of eight Hyalopontius species have thus far been collected only between 1900 and 4060 m depth in the Northeast Atlantic (HÜLSEMANN 1965, BOXSHALL 1979).

Specimens of the misophrioid genus Benthomisophria SARS increased in numerical abundance with depth (Fig. 9). According to BOXSHALL & ROE (1980), two species, B. palliata and B. cornuta, inhabit depths from 2000 m to the bottom and increase in abundance within the 500 m of the sea floor. The data presented here corroborate this.

### 3.5. Concluding remarks

The general decrease in zooplankton abundance with depth in the deep sea may be reversed, at least locally or temporarily, close to the bottom (WISHNER 1980a; ANGEL & BAKER 1982; ROE 1986). The taxonomic composition changes abruptly near the bottom since there are many species endemic to benthopelagic habitats (GRICE 1972; WISHNER 1980b; ROE 1986). A comparison of the BIOTRANS data between 200 and 1500 m from the abyssal bottom with those from within 100 m of the sea floor (WISHNER 1980b, SMITH *et al.* 1986) indicates fundamental changes in the relative abundances of the major groups that occur about 100 to 200 m above the deep-sea floor. More than 200 m from the bottom, chaetognaths and ostracods follow copepods in order of abundance, while just above the bottom, Malacostraca seem to be next important.

The data from this investigation also indicate vertical changes in the zooplankton community structure within the upper parts of the bottom nepheloid layer. The relative proximity of the sea bed may be a contributing cause of this, even at this fairly great distance. Vertical gradients can be detected for small taxonomic groups and are probably less pronounced than those within 100 or 200 m of the bottom. A comprehensive evaluation of vertical faunal zonation in the deep bathyal and abyssal plankton communities, however, requires an analysis on the specific level. Relevant results from directly overlying depths indicate associated changes in predator-prey relationships. In profiles from the bathyal Northeast Atlantic, ANGEL (1983) found marked changes in the species composition of the ostracod fauna coinciding with changes in the abundance of different predatory micronektonic groups at depths of 1900, 2200, 2700, and 3500 m.

##### 5. ACKNOWLEDGEMENTS

The author thanks the officers and crew of the RV "Polarstern" for their kind cooperation. C. Schumacher and A. Plaga helped with the time consuming sampling. I am also indebted to C. Schumacher for the careful preservation of the material; to A. Plaga, for pre-sorting the samples; to R. Velten and S. Luck, for providing the drawings; and to Dr. H. Weikert, for critically reading the manuscript. Dr. C. Heckman improved the English text. Dr. I. Hempel, Bremerhaven, kindly offered me to publish the data lists in this journal. The Ministry of Science and Technology of the Federal Republic of Germany funded the investigations (MFU 0544/9).

## 6. APPENDIX

### 6.1. Remarks

In the following tables, the numerical counts of living, dead, and contaminant specimens belonging to various taxa in each of the 30 MOCNESS-samples are presented. Some explanatory comments on different groups are necessary.

Foraminiferans were considered to be contaminants, as most of them were very small. Radiolarians, which are more common in the deep sea, were often broken and could not be counted in many cases. They are therefore excluded from the numerical data on total zooplankton. An "x" in the tables indicates that specimens were present but not counted.

Other taxa, such as Ostracoda and Chaetognatha, surely include some contaminants from surface water layers, but only a more detailed taxonomic evaluation will yield exact information. All specimens in these groups were counted as living, so their relative abundances and total numbers in the zooplankton may be somewhat overestimated. Relative abundances of other taxa are correspondingly underrated.

Ostracods were often fragmented. In most samples, the valves were more numerous than the internal remains of the animals. The counts include only complete specimens and internal remains. No attempt was made to estimate the number of "dead" ostracods. Specimens of hyperiid amphipods were considered contaminants.

A fairly good separation of autochthonous from contaminant specimens and living animals from carcasses and exoskeletons was possible for copepods. The numbers of dead animals include those of taxa considered to be contaminants from shallower layers.

Harpacticoid contaminants included specimens of the genus Microsetella, while most of the endemic living and dead animals could be assigned to the genus Aegisthus. Living Oithonidae, Oncaeidae, and Corycaeidae were regarded as contaminants in view of their small body sizes and relatively great abundances in shallower layers (BECKMANN, unpublished data). A few isolated Mormonilla specimens were included in the cyclopoid counts.

Among the living Calanoida, some small unidentified epipelagic forms were considered to be contaminants along with individuals of the following taxa:

- Genus Calanus (Fam. Calanidae)
- Genus Eucalanus, Rhincalanus nasutus GIESBRECHT (Fam. Eucalanidae)

- Mecynocera clausi THOMPSON (Fam. Calocalanidae)
- Genus Centropages (Fam. Centropagidae)
- Genus Pleuromamma (mainly P. gracilis CLAUS) and Metridia lucens BOECK (Fam. Metridiidae)
- Lucicutia flavigornis CLAUS (Fam. Lucicutiidae)
- Family Candaciidae
- Genus Acartia (Fam. Acartiidae)

Euthecosomatous pteropods were represented mainly by empty shells of the species Limacina retroversa FLEMING.

The following abbreviations are used in the data lists:

- No.liv : Number of specimens counted as "living"
- %tz : Relative abundance among total living zooplankton (only values  $\geq 2\%$  considered)
- %cal : Relative abundance among living calanoid copepods (only values  $\geq 2\%$  considered)
- No.ex : Number of exoskeletons (molt and organisms dead at the time of capture) or empty shells (Pteropoda, Euthecosomata)
- No.cont : Number of living specimens regarded as contaminants from shallower layers.

## Folgende Hefte der Reihe „Berichte zur Polarforschung“ sind bisher erschienen:

Verkaufspreis/DM

* <b>Sonderheft Nr. 1/1981</b> – „Die Antarktis und ihr Lebensraum“ Eine Einführung für Besucher – Herausgegeben im Auftrag von SCAR	
<b>Heft Nr. 1/1982</b> – „Die Filchner-Schelfeis-Expedition 1980/1981“ zusammengestellt von Heinz Kohnen	11,50
<b>Heft Nr. 2/1982</b> – „Deutsche Antarktis-Expedition 1980/1981 mit FS ‚Meteor‘“ First International BIOMASS Experiment (FIBEX) – Liste der Zooplankton- und Mikronektonnetzfänge zusammengestellt von Norbert Klages	10,—
<b>Heft Nr. 3/1982</b> – „Digitale und analoge Krill-Echolot-Rohdatenerfassung an Bord des Forschungsschiffes ‚Meteor‘“ (im Rahmen von FIBEX 1980/81, Fahrtabschnitt ANT III), von Bodo Morgenstern	19,50
<b>Heft Nr. 4/1982</b> – „Filchner-Schelfeis-Expedition 1980/81“ Liste der Planktonfänge und Lichtstärkemessungen zusammengestellt von Gerd Hubold und H. Eberhard Drescher	12,50
* <b>Heft Nr. 5/1982</b> – „Joint Biological Expedition on RRS ‘John Biscoe’, February 1982“ by G. Hempel and R. B. Heywood	
* <b>Heft Nr. 6/1982</b> – „Antarktis-Expedition 1981/1982 (Unternehmen ‚Eiswarte‘)“ zusammengestellt von Gode Gravenhorst	
<b>Heft Nr. 7/1982</b> – „Marin-Biologisches Begleitprogramm zur Standorterkundung 1979/80 mit MS ‚Polar-sirkel‘ (Pre-Site Survey)“ – Stationslisten der Mikronekton- und Zooplanktonfänge sowie der Bodenfischerei zusammengestellt von R. Schneppenheim	13,—
<b>Heft Nr. 8/1983</b> – „The Post-Fibex Data Interpretation Workshop“ by D. L. Cram and J.-C. Freytag with the collaboration of J. W. Schmidt, M. Mall, R. Kresse, T. Schwinghammer	10,—
<b>Heft Nr. 9/1983</b> – „Distribution of some groups of zooplankton in the inner Weddell Sea in summer 1979/80“ by I. Hempel, G. Hubold, B. Kaczmaruk, R. Keller, R. Weigmann-Haass	15,—
<b>Heft Nr. 10/1983</b> – „Fluor im antarktischen Ökosystem“ – DFG-Symposium November 1982 zusammengestellt von Dieter Adelung	23,—
<b>Heft Nr. 11/1983</b> – „Joint Biological Expedition on RRS ‘John Biscoe’, February 1982 (II)“ Data of micronecton and zooplankton hauls, by Uwe Piatkowski	16,—
<b>Heft Nr. 12/1983</b> – „Das biologische Programm der ANTARKTIS-I-Expedition 1983 mit FS ‚Polarstern‘“ Stationslisten der Plankton-, Benthos- und Grundsleppnetzfänge und Liste der Probennahme an Robben und Vögeln, von H. E. Drescher, G. Hubold, U. Piatkowski, J. Plötz and J. Voß	14,—
* <b>Heft Nr. 13/1983</b> – „Die Antarktis-Expedition von MS ‚Polarbjörn‘ 1982/83“ (Sommercampagne zur Atka-Bucht und zu den Kraul-Bergen), zusammengestellt von Heinz Kohnen	
* <b>Sonderheft Nr. 2/1983</b> – „Die erste Antarktis-Expedition von FS ‚Polarstern‘ (Kapstadt, 20. Januar 1983 – Rio de Janeiro, 25. März 1983)“, Bericht des Fahrtleiters Prof. Dr. Gotthilf Hempel	
* <b>Sonderheft Nr. 3/1983</b> – „Sicherheit und Überleben bei Polarexpeditionen“ zusammengestellt von Heinz Kohnen	
<b>Heft Nr. 14/1983</b> – „Die erste Antarktis-Expedition (ANTARKTIS I) von FS ‚Polarstern‘ 1982/83“ herausgegeben von Gotthilf Hempel	40,—
<b>Sonderheft Nr. 4/1983</b> – „On the Biology of Krill <i>Euphausia superba</i> “ – Proceedings of the Seminar and Report of the Krill Ecology Group, Bremerhaven 12.–16. May 1983, edited by S. B. Schnack	75,—
<b>Heft Nr. 15/1983</b> – „German Antarctic Expedition 1980/81 with FRV ‘Walther Herwig’ and RV ‘Meteor’“ – First International BIOMASS Experiment (FIBEX) – Data of micronektion and zooplankton hauls by Uwe Piatkowski and Norbert Klages	22,50
<b>Sonderheft Nr. 5/1984</b> – „The observatories of the Georg-von-Neumayer-Station“, by Ernst Augstein	8,—
<b>Heft Nr. 16/1984</b> – „FIBEX cruise zooplankton data“ by U. Piatkowski, I. Hempel and S. Rakusa-Suszczewski	19,—
<b>Heft Nr. 17/1984</b> – „Fahrtbericht (cruise report) der ‚Polarstern‘-Reise ARKTIS I, 1983“ von E. Augstein, G. Hempel und J. Thiede	29,—
<b>Heft Nr. 18/1984</b> – „Die Expedition ANTARKTIS II mit FS ‚Polarstern‘ 1983/84“, Bericht von den Fahrtabschnitten 1, 2 und 3, herausgegeben von D. Fütterer	25,—
<b>Heft Nr. 19/1984</b> – „Die Expedition ANTARKTIS II mit FS ‚Polarstern‘ 1983/84“, Bericht vom Fahrtabschnitt 4, Punta Arenas–Kapstadt (ANT-II/4), herausgegeben von H. Kohnen	41,—
<b>Heft Nr. 20/1984</b> – „Die Expedition ARKTIS II des FS ‚Polarstern‘ 1984, mit Beiträgen des FS ‚Valdivia‘ und des Forschungsflugzeuges ‚Falcon 20‘ zum Marginal Ice Zone Experiment 1984 (MIZEX)“ von E. Augstein, G. Hempel, J. Schwarz, J. Thiede und W. Weigel	42,—
